SIR,—Your annotation on loneliness in infancy (Sept. 19, p. 345) is, to my mind, the most important you have published over a long period. "In infancy loneliness may be not only undesirable but lethal." Doctors who are specifically concerned with physical diseases may think it odd that this particular leader should be picked out for emphasis, but if medicine is to interest itself in the emotional as well as the physical roots of health, simple facts such as those that are stated in this article are fundamental.

The value of long unhurried analyses of a few patients by highly trained psycho-analysts is, sociologically, only in the scientific results obtained, but the application of the advances of our knowledge of human emotional development has direct sociological value. No advance in this knowledge is more significant to-day than the recognition of the strength of the relationship between mother and infant, even newly born.

The sort of experience which Dr. Bakwin describes in the article which forms the stimulus for the leader indeed makes one shudder, and it is a matter for regret that it is as an indirect result of gross human error that your comments appear, instead of as a direct result of good understanding. Nevertheless, these comments are welcome, and the strength of the word "lethal" may perhaps draw attention to the fact that we cannot take mothers from their babies (for war work) without killing infants. The truth is worse than this. We cannot take mothers from infants without seriously increasing the psychological burdens which the next generation will have to bear. We even know that it is the psychotic defectives and the delinquents of the next decade who are being recruited by this, perhaps the worst of the many silly things Hitler is making us do.—I am, etc.,

London, W.1. D. W. WINNICOTT.

Enuresis in Children

SIR,—Dr. J. J. Walls wonders if the aboriginal races are normally enuretic (May 16, p. 622). Recently a Zulu woman brought her child to me for treatment for enuresis. She looked upon it as something abnormal. I quote the following from the section on infancy in a book (O. F. Raum, *Chaga Childhood*, p. 109) which describes a tribe living in Tanganyika Territory: "Enuresis calls forth a variety of measures. The steps taken with smaller children are magical. When a baby is about

---

[1] *Les Plaies de Guerre du Poumon*, par Pierre Duval, Paris: Masson et Cie, 1917; *War Wounds of the Lung*, by Pierre Duval, Bristol: John Wright and Sons, 1918.

9 months old its mother collects drops of rain in the hoof of a goat or the involutions of a colocasia leaf. This she gives to the child as a medicine, saying, 'Take and drink this drug. It will keep you from wetting the bed!' A bigger child is shown the puddle and scolded. . . . Boys are warned that unless they mend their ways they will not be allowed to sleep in their father's hut. . . . But some children never learn to control urination, though they are scorned for their deficiency and told that this will be an obstacle to their marriage (enuresis is a ground for divorce)."—I am, etc.,

Pietermaritzburg HELEN F. H. RAUM.

Lister's Antiseptic Technique

SIR,—I think it was in 1867 that Lister introduced the antiseptic method of dealing with wounds in the wards of the Glasgow Royal Infirmary. He used carbolic acid as his antiseptic. Later, I believe, he tried the bichloride of mercury, but reverted to carbolic acid after his colleague, Prof. Crookshanks of King's College, London, reported more favourably on the use of carbolic acid.

Lister reduced the technique of a surgical operation to the utmost simplicity. He taught that a solution of 1 in 20 of carbolic acid, if used for the hands, the sutures and ligatures, the skin of the patient, and for the wound itself, would make the operation safe so far as sepsis is concerned. He even taught that for scalp wounds it was not necessary to remove the hair if carbolic acid was employed, as the hair had a strong affinity for the carbolic acid and became itself an antiseptic dressing. Lister went so far as to say that the solution (1 in 20) of carbolic acid could be made when the surgeon arrived at the operating room, that sutures, knives, etc., could be immersed in the solution, and that they would be then quite safe to use after a matter of 10 to 15 minutes.

Carbolic acid was the antiseptic used in the Western Infirmary, Glasgow, when I was a student in 1885-8. It must be confessed that the results there were not so good as Lister's, chiefly, I believe, because the eminent surgeons (except perhaps Hector Cameron, who had been assistant to Lister in Glasgow) did not whole-heartedly believe in the germ theory of sepsis, and taught in my time that even pus might be laudable, or not laudable, according to its colour, etc. Twice only in the three years I was a student at the Western Infirmary did I see the abdomen opened. One patient, who was operated on for a tubal pregnancy by Hector Cameron (later Sir Hector), recovered; the other died. The surgeons then believed that opening the abdomen was not a justifiable operation.

I believe the surgeons of the future will be forced to employ both methods in operation—the aseptic and the antiseptic technique—the aseptic to disinfect dressings and instruments, and the antiseptic to disinfect the skin of the patient, the sutures and ligatures, and the wound itself before closing it to prevent what I consider a serious defect in aseptic surgery—namely, aerial infection—which, I fancy, is responsible for many of those mysterious deaths that occur two or three weeks after a so-called successful operation.

I may say that, as a G.P., I have used during the last 50 years the bichloride of mercury (1 in 1,000 or 2,000) solution, and it has never let me down. It is the custom now to "débride" all ragged wounds. A boy ripped his foreleg with a bicycle pedal from the knee to the ankle. Having no one to give him chloroform, I swabbed out the wound thoroughly with bichloride of mercury solution (1 in 1,000), and, placing the sutures for several minutes in the solution, I put 12 sutures in the leg. Not a single drop of pus formed around the stitches. This was Lister's method, but with the bichloride of mercury solution instead of carbolic acid.—I am, etc.,

Dornoch. J. T. MACLACHLAN.

Fallacies concerning Rehabilitation

SIR,—Rehabilitation is fast becoming the popular tag in medical circles in this war, but, like similar tags on previous occasions, it is only too apt to become encrusted with misconceptions. Two such misconceptions are already gaining ground. The first is that rehabilitation represents some new method of treatment hitherto confined to a limited selection of mental and orthopaedic patients. The second is that it is essentially a post-hospital problem, best tackled in specially equipped rehabilitation centres. I think it is of the utmost importance that both these misconceptions should be vigorously countered.

Rehabilitation is not a new method of treatment at all. It is the application to all types of recent disability of those varied methods of supervised exercise which exponents of physical medicine have advocated for years. What is new about it—at any rate in some circles—is the discovery that these methods are best applied and with greatest hope of success during the very first days after injury or operation instead of following a long period of immobilization; that remedial exercises, muscular drill, weight and pulley tests, occupational therapy, and organized games can all make specific contributions towards the recovery of muscular tone and the restoration of painless joint movement; and the rehabilitation should be conceived as a single process in which all these various methods act in combination and do not follow one another in order of time.

The other fallacy, that rehabilitation should best be carried out at specially equipped centres after the patient's discharge from hospital, is dangerous, as it tends to obscure the essential fact that rehabilitation is as much part of the proper treatment of an injury or illness as is the setting of a fracture, the repair of a hernia, or the dressing of an empyema, and that adequate steps ought to be taken from the very outset, not merely to treat the complaint but also to anticipate and prevent any subsequent disability.

We have now had some months' experience of rehabilitation methods in this emergency hospital, and the advantages of carrying out such measures on the spot instead of waiting for transfer to a separate rehabilitation centre have been most striking. It has meant that supervised physical exercises have been planned for every type of patient and adapted to the particular disability to be overcome; that suitable muscular drill has been carried out in bed on thoracic and abdominal patients, cartilage operations, fractures, and the like; that results are already showing earlier and better union of fractures and more rapid restoration of muscular power and joint flexibility, all varying with the rapidity with which such exercises can be started after the injury; that the whole morale and spirits of the patients have been raised, as they have watched their own progress from day to day and kept their own graphs; and that patients have been leaving the hospital and rejoining their units at an earlier date and in far fitter condition than was previously the case. It is time that rehabilitation methods were accorded a place in the routine treatment of all hospital patients whose illness or injury predisposes to subsequent weakness or disability.—I am, etc.,

HAROLD BALME,
Medical Superintendent,
Pinderfields Emergency Hospital.

Splenectomy in Purpura Haemorrhagica

SIR,—My comment on Dr. Bruce Williamson's letter (Oct. 3, p. 407) must be that if a manual worker is unable to follow his employment or a young woman's life is jeopardized by menorrhagia because of chronic thrombocytopenic purpura, I should feel I had failed in my duty if I did not recommend splenectomy. This is not a question of clinical experiment but of orthodox haematology and therapeutics. Recent data and references are given by N. Rosenthal (*J. Amer. med. Ass.*, 1939, **112**, 101). It is true that the results of operation are sometimes disappointing, but Dr. Bruce Williamson paints far too gloomy a picture.—I am, etc.,

The Radcliffe Infirmary, Oxford L. J. WITTS.

SIR,—Under the above heading Dr. Bruce Williamson (Oct. 3, p. 407) refers to an article in the *Journal* of Sept. 12 (p. 309) by Prof. Witts. My experience of what is called "essential purpura haemorrhagica" and the effect of splenectomy as a curative measure does not agree with that of Dr. Williamson, as I have previously expressed at meetings of the Clinical Section of the Royal Society of Medicine, and more particularly in an article in your columns on Sept. 7, 1935 (p. 445). In the series of cases which are therein mentioned no case was accepted unless the capillary resistance test was positive, and Mr. Rodney Maingot, who collaborated with me, never regretted this attitude, for, so far as we can ascertain at present, all our cases in which splenectomy has been performed by Mr. Maingot have had no recurrence of symptoms, and it is 16 years since the first 3 were operated on. We can, however, only give this assurance up to the beginning of the war, but all the patients had promised to write to me if any further symptoms occurred. If one of our patients should show recurrence I should suspect the presence of a splenculus which had grown to full size and advise an operation to verify this statement and to remove the accessory spleen.

Under the heading of "Diagnosis," in the article referred to, I wrote: "One might describe essential purpura haemorrhagica as an idiopathic disease, which may be acute or chronic and intermittent. It is characterized by the appearance of purpuric spots on the skin and spontaneous haemorrhages from one or more mucous surfaces—often resulting in anaemia—in which there are prolonged bleeding time, distinct diminution in the number of platelets, a positive capillary resistance test, generally a normal coagulation time, and a flat blood clot. The differential diagnosis has to be made from haemophilia, aplastic anaemia, lymphatic leukaemia, scurvy, hereditary haemorrhagic telangiectasis, and also from symptomatic purpura and hereditary thrombasthenic purpura. The points of importance are the personal and family history, the clinical history of the case, the performance of careful clinical examination, complete blood investigation, and the various tests mentioned above, such as bleeding time, coagulation time, etc. A proper appreciation of the information afforded should determine the diagnosis." I publish this in full for I feel that some reporters of cases may be alluding to a different condition with certain similarities to the genuine cases.—I am, etc.,

London, W.1. BERNARD MYERS.

Foreign Bodies in the Alimentary Tract

SIR,—I have read Mr. G. O. Chambers's article (Sept. 26, p. 362) with great interest, for he has given details of a most remarkable series of cases, but I trust that his experience is unusual. I have made many *x*-ray examinations on persons who have swallowed foreign bodies and have been frequently responsible for their treatment, but I have known only 5 cases which were followed by perforation, and in all 5 perforation could be attributed to an error in diagnosis or treatment.

Any person who is suspected of swallowing a foreign body should be examined as soon as possible and the exact position of the foreign body determined. If it is held up in the pharynx or oesophagus it should be removed, for though it may pass naturally the patient is in imminent danger of perforation. The patient should never be given an emetic, for such actions as vomiting, retching, or swallowing may cause further impaction. Once the foreign body is shown to be in the stomach there is no immediate cause for anxiety, for the majority of foreign bodies, which are swallowed accidentally will pass naturally, as will many of those swallowed by mental defectives. So far as is possible the patient should live under natural conditions. Generally he can be allowed to go home, providing he is kept under daily observation and there is easy access to a hospital. His diet should be unrestricted, for food is the natural stimulant of alimentary movements, and on no account should he be given a purgative, for the irritation so caused may excite spasm and lead to impaction or perforation. In most cases the foreign body will pass through the alimentary canal within a week, but occasionally it may be held up.

Sometimes the foreign body is retained in the stomach. If it is quite free the hold-up is due to inability of the musculature to lift the body towards the pylorus, and this difficulty is usually overcome by keeping the patient lying on his right side, or by total starvation for 24 hours. A hold-up in the antral region of the stomach, the pyloric canal, the duodenum, or the proximal coils of the small bowel for 24 hours suggests impaction, for in these situations the bowel is normally vigorously active. Such a case should be kept under observation by a surgeon. A persistent hold-up in the terminal ileum is unusual, and is most apt to occur if the patient is starved or very constipated, and may be relieved by adjusting the diet or by a small enema. If the body is small enough to enter the appendix it may be retained there for years, but fortunately this complication seldom arises. A hold-up in the colon is usually due to starvation or constipation. The patient should take liberal quantities of vegetable foods but on no account be given a purgative or enema, for so long as the foreign body moves slowly along the bowel the patient is in no danger.

Two of the 5 cases previously mentioned were in children, in whom perforation of the oesophagus occurred, the foreign bodies having been missed owing to the *x*-ray examinations being confined to films of the abdomen. In one case there was perforation of the stomach, the patient having been given a purgative which made him sick; one was due to radium necrosis of the appendix 3 days after hold-up of a 1 mg. radium needle; and one patient had an ischio-rectal abscess from penetration of the rectum after an enema had been given.—I am, etc.,

Radcliffe Infirmary, Oxford. F. H. KEMP.

Narco-analysis for War Neuroses

SIR,—I have been very much interested in Dr. J. L. Clegg's experiences with pentothal narco-analysis (Aug. 1, p. 140) and in comparing them with my own. I am happy to find myself almost in complete agreement with his conclusions, though I "hand him the palm" for enthusiasm, as he has employed the technique in four times the number of my cases over a similar period.

Narco-analysis has, of course, a very limited application, and is to a large extent a confession that other psychotherapeutic efforts, quickly applied, have failed. I only use it or advocate its use in cases where a definite impasse has been reached in endeavouring to overcome a patient's resistance. A therapist's value to a psychological unit depends on his ability to overcome resistance. Dr. Clegg has probably found, as I have, that this ability on the part of his assistants and collaborators, whether as the result of inherent gifts of healing or of extensive postgraduate training, or both, is very unevenly distributed. It is extremely valuable in suitable patients to be able to fall back on a more objective method, by which results are then achieved and much time saved.

Hypno-analysis I have found extremely useful in many cases, particularly in hysterical subjects. My experience with acute and chronic anxiety states, which form a large proportion of our war neuroses, has been identical with Dr. Clegg's. These patients cannot give the concentration necessary for the induction of hypnosis, and are, therefore, more suitable for other techniques, including narco-analysis.

Narco-analysis is not in itself a means of producing a positive transference; it may often produce a negative one. If, however, a positive transference has already been established in early interviews it is not necessarily disturbed by the technique. Patients who have benefited often ask for repeated doses, and persuade their comrades to submit to the treatment.

It has been gratifying in this discussion to have the support of Dr. J. S. Horsley (Aug. 22, p. 230), who originated the term for this technique and was its pioneer in these islands. I share his hope that real progress will be made in the Services towards perfecting it, so that we may advance from the inadequacy of stereotyped methods. To Dr. H. Crichton-Miller (Aug. 22, p. 230) I am obliged for stressing the saving of time effected by this method and for illustrating by case histories how relatively unimportant it is whether hidden material is repressed or merely withheld. From the therapeutic point of view it does not matter whether the patient's amnesia is true or false. The important thing is to achieve "abreaction" and liberate pent-up emotions, be the suppressing or repressing forces conscious, semi-conscious, or unconscious.—I am, etc.,

J. F. WILDE,
Major, R.A.M.C.

Anaemia in Young Adults—Dietetic?

SIR,—May I, a surgeon, with all humility air a medical observation in your columns. During the past year I have had several cases among my out-patients of a fairly severe anaemia arising in otherwise healthy young adults. Most of the subjects were the victims of small accidents—a sprained ankle or cut finger—which brought them to my clinics. Two at least had had a simple appendicectomy. The complaints made were identical in all the cases: dizziness with weakness and aching of the legs. On examination the patients were pale with pallor of the mucous membranes, had a well-marked "bruit de diable" at the root of the neck, and had a blood picture showing an anaemia with a deficit of red cells of one to two and a half millions, a colour index well below 1, and no other significant changes. A short course of iron rapidly cured them all. Although my hospitals are situated in fairly poor districts, all the patients were above the poverty line.

With the exception of two housewives, all were in good jobs and all were on the young side of 40.

I should like to know whether this apparently dietetic anaemia has been noticed elsewhere, and would also like confirmation from the experts of my view that it is a lineal descendant of the old-fashioned "chlorosis" of our fathers. If this is so, and the condition proves to be at all widespread, might I suggest that it arises from the cutting down of our meat ration with a consequent shortage of organic iron of the right chemical constitution in our diet? Further, I would suggest that the Ministry of Food might well consider the rationing of such articles as liver and the starting of a campaign to popularize the consumption of "black pudding" and other blood foods.—I am, etc.,

Wimbledon, S.W. 20. A. J. Hobson, F.R.C.S.

Blood Donors

Sir,—I have read with interest Dr. L. W. Proger's article (Aug. 29, p. 252). In it he fails to acknowledge the help this scheme has had and still has from the large number of voluntary workers throughout the country. It was not until the war had continued for over a year that the Provinces at any rate received any help in their individual and uncoordinated endeavours to maintain an adequate transfusion service. Up to that time most of us had spent much time, trouble, and money in training ourselves and obtaining equipment for our own needs. Since then we have had in this area much help from our regional transfusion centre, but the assistance received from the Ministry in the way of money for expenses and publicity is pathetic. The maximum financial aid allowed is 6d. per donor per annum. This is said to cover clerical expenses. Nothing is received for travelling expenses of donors, refreshment, apparatus, and iron therapy. The work of the medical officers and their helpers has always been voluntary.

It is probably a common experience of us all, as Dr. Proger mentions in his article, that frequently 50% of donors who are asked to attend fail to appear. Such apathy could be counteracted by some full-blooded propaganda by the Government. So far this propaganda has been limited to the issue of a few very indifferent posters. Finally, I would appeal to the medical branches of the Services for the provision of donors. If the giving of blood incapacitates the fit soldier, it surely must have a more adverse effect on the hard-pressed munition worker. Personally, I can see no reason at all why the Forces who have so much interest in this service should not provide a large part of the raw material.—I am, etc.,

E. Biddle,
Transfusion Officer.
East Suffolk and Ipswich Hospital.

Sulphonamide Sunlight Eruptions

Sir,—With reference to the article on sulphonamide sunlight eruptions by Capts. R. G. Park and W. M. Platts (Sept. 12, p. 308), I should like to submit to you the following considerations.

Because of structural similarities, sulphonamides are substituted for *p*-aminobenzoic acid, an essential metabolite of micro-organisms, and become germicides consequently. But *p*-aminobenzoic acid is an important constituent of the host's organism as well, especially of the vitamin B complex. Thus sulphonamides belong to the group of poisonous substances interfering with the activity of B complex—e.g., indole, nicotine, and extract of ground fresh fish. Park and Platts emphasize: "In their power to cause an eruption in parts previously exposed to the sun sulphonamides resemble pellagra."

Impairment of B complex is dangerous because parts of the complex are components of enzymes and ferments; nicotinamide is part of cozymase of v. Euler and of the coferment of Warburg; thiamine pyrophosphate (cocarboxylase) is another important coenzyme; riboflavin phosphorylate attached to a specific protein is the yellow enzyme of Warburg-Christian.

We see that the components of B complex control respiration, metabolism, cell repair, cell reproduction, cell proliferation; they may be the pathogenetic source of many diseases of well-known and unknown aetiology, even of psychoses—e.g., schizophrenia—and cancer. That we may become able to turn the wrong cell metabolism to the right way is a hope, but partly a fact, as the reports of Spies (*J. Amer. med. Ass.*, 1939, **113**, 931), Sydenstricker (ibid., p. 1697), Cleckley (ibid., **112**, 210), and many other authors show.—I am, etc.,

Cambridge. G. Brock, M.D.

Tenosynovitis in Industrial Workers

Sir,—In their article on tenosynovitis (Sept. 26, p. 367) Lieut.-Col. R. E. Flowerdew and Dr. O. B. Bode bring out several points that can bear emphasis. As a works medical officer I see a fair number of these cases every year, and I have noticed the following points which may be of interest to others. With the influx of new workers into my industry tenosynovitis has increased, and I saw 50% more cases in 1941 than in 1940; the number of employees was approximately the same and the processes were unaltered. The tendons affected are usually the extensor ossis metacarpi pollicis and the extensor brevis pollicis, and the movements which produce the complaint appear to be a combination of grasping an object by thumb and fingers, followed by quick pronation, as in closing the lid of a box.

Newcomers to a repetitive, stereotyped job involving these movements are particularly vulnerable, but it is to be noticed that cases crop up among employees who have had years of experience at these jobs, particularly after returning to work following a holiday or sick leave. It is decidedly rare in my experience for a patient who has fully recovered to relapse on returning to the same job. The period of disability in my cases is approximately the same—namely, 7 to 10 days—but it is essential, if the period is to be kept at this figure, to insist on the patient ceasing work as soon as the diagnosis is made. I have never seen a patient recover if kept at the same job that produced the condition, whatever the local treatment adopted.

In my early days I saw many patients get worse, and they had to be put off work; in these cases the recovery period was nearly always much greater. I have no reason to change the opinion expressed by me in the *Practitioner* in 1938—namely, that whatever local treatment is used rest is essential. The treatment I use is to strap the affected wrist with elastoplast, starting with a couple of turns round the hand and working up the wrist until the swelling is covered. This strapping is left on for 1 week after the patient has returned to work. The condition appears to be an inflammatory response to excessive fatigue of various groups of muscles, particularly those crossing the dorsum of the wrists. It also occurs in the anterior tibial group and the tendo Achillis.—I am, etc.,

Cadby Hall, W. 14. W. Blood.

What is a Closed Profession?

Sir,—Apropos of the very welcome recommendation that nursing should be made a "closed profession," what, exactly, is a "closed profession"? Since any unqualified and unregistered persons are free to practise medicine, surgery, and midwifery provided they do not represent themselves as qualified medical practitioners, sign death certificates, attempt to recover fees in the courts, etc., is there anything to prevent a class of unqualified, unregistered women from "tending sick persons for rewards"—whether under the direction of a medical practitioner or not—notwithstanding the passing of a "Nursing Act": in other words, of standing in the same relationship to the nursing profession as chemists, herbalists, "health practitioners," and the rest, do to the medical profession? Is medicine a "closed profession"? If so, it seems to leak badly.

If the Government takes over all medical practitioners, lock, stock, and barrel, as some seem to hope, will unqualified practice still be permitted or will it be regarded as an infringement? Has the individual any common law right to be treated by an unqualified practitioner if he desires it?—I am, etc.,

Brookwood, Surrey. H. M. Stanley Turner.

Operations, and Workmen's Compensation

Sir,—In reply to Prof. H. Levy's letter (Sept. 26, p. 380) I think all I need say is that I am fully aware of the nature of the evidence given by the British Medical Association before the Royal Commission on the Workmen's Compensation Act; that I had read the report of the combined medical and legal meeting at the Royal Society of Medicine some months ago;

hat I have had practical experience of the interpretation and application of the W.C.A. for the last twenty-five years, not only in the county courts but for twenty years as chief medical officer in London for the South-Eastern and Chatham and ater the Southern Railway; that I am fully aware of the great value of the special methods employed in rehabilitation centres; that I hold no brief (as explained in my first letter) for the W.C.A.; and that my sole object in my last letter was to correct what I believe to be rather widespread misapprehensions as to the provisions of the Act.—I am, etc.,

London, W.1. H. GARDINER.

*** This correspondence is now closed.—ED., *B.M.J.*

Scientific Journals for Enemy Prisoners of War

SIR,—I was interested to note the facilities given to prisoners of war in Germany to submit an article on typhus to the *British Medical Journal.* It may not be generally known that in order to prevent mental stagnation among enemy prisoner scientists in this country some efforts are being made to send them unwanted reprints of scientific articles. The authorities have welcomed the scheme, realizing that when world law and order are restored some of these very able men may, by their skill, play some part by scientific discovery to mitigate the physical ills of mankind. J. R. Baker, in acknowledging copies of the *B.M.J.* sent to the Department of Zoology and Comparative Anatomy, University Museum, Oxford, writes: "These are *particularly* welcome, because most of the people concerned are medical men."—I am, etc.,

Kelly College, Tavistock. A. ADAIR.

*** Dr. John R. Baker, writing from Burnt Oak, Kidlington, nr. Oxford, to *Nature* (Oct. 3), appeals for reprints of articles or copies of scientific journals to be sent to him at that address. Donors should give their names and addresses, so that they may receive acknowledgment and a report on the progress of the scheme.—ED., *B.M.J.*

Tongue Sign in Louse-borne Typhus Fever

SIR,—The symptomatology of louse-borne typhus fever described by Capts. C. Donald and P. B. Barker (Sept. 19, p. 333), embodying their experiences in a German prison camp during February, 1942, recalled to my mind a sign to which we in Poland attached some significance. It is the tongue sign, first described by Sterling-Okuniewski in his monograph on typhus. The patient is unable to put out his tongue when ordered to do so, especially in cases where the central nervous system is involved. The reason is perivascular infiltration in the region of the nucleus of the hypoglossal nerve. We found this simple clinical test of great help in differential diagnosis, especially since epidemics of typhus and enteric fever often occur simultaneously in Poland.—I am, etc.,

London, W 1. H. KRYSZEK, M.D.Cracow.

Obituary

M. BODLEY SCOTT, O.B.E., F.R.C.S.Ed.

The sudden death of Maitland Bodley Scott on Sept. 29, at the age of 64, came as a great shock to his many medical friends; he had seemed perfectly well when operating at Blandford Cottage Hospital two hours before. He was a native of Bournemouth and had an extensive surgical practice in his home town and in the surrounding districts, particularly in the Blandford area. From Marlborough he went to St. Bartholomew's Hospital, where his father and grandfather had been and to which he sent his eldest son. Scott served on the active staff of the Royal Victoria and West Hants Hospital from 1907 until 1938, when, on reaching the age limit, he was elected consulting surgeon. While assistant surgeon he organized, and was placed in charge of, the orthopaedic department, and while senior surgeon he initiated and supervised the fracture department. He was also honorary surgeon to Blandford Cottage Hospital, in which he took a deep interest; it was largely due to his devoted work and organizing skill that this hospital rose to its present high standard of efficiency. When the last war started he went to St. Malo to organize a Red Cross hospital for the French wounded. When it was taken over by the French he joined the Royal Navy and spent two years in Russia, serving under Commander Locker-Lampson; on his return he transferred to the R.A.M.C. with the rank of major and served in Mesopotamia as surgical specialist in the "Dunsterforce." For the work he did there he was awarded the O.B.E. (Military). At the outbreak of the present war he resumed active work at the R.V. and W.H. Hospital. His organizing ability and unstinted energy played a major part in the Emergency Hospital arrangements, not only in Bournemouth but at Blandford and Fairmile Hospital, Christchurch, where he did excellent work. Despite all these activities he was a regular attendant at the local medical war committee meetings.

Scott, a man of few words, never courted publicity, but the obvious wisdom of his concise observations carried much weight at the many committees on which he sat. He had great manual dexterity and a highly developed mechanical sense; his main hobbies were carpentry and architecture: it is therefore not surprising that it was a pure joy to watch his bone surgery. He never hesitated during an operation; never handled the tissues roughly; never scamped detail or appeared to hurry; yet he was a remarkably quick operator. His loss will be deeply felt by all who came in contact with him; he pulled his full weight to the day of his death. He leaves a widow and six sons, five of whom are on active service with the Forces.

A. B. R.

G. A. EWART, F.R.C.S.

We have to announce with regret the sudden death on Oct. 2 at Weybridge of Mr. George Arthur Ewart, surgeon to St. George's Hospital. He was the only son of the late James Cossar Ewart, M.D., F.R.S., for 45 years regius professor of natural history at Edinburgh, and was born on June 1, 1886. He was educated at Cargilfield, Clifton College, Edinburgh University, and Christ's College, Cambridge (of which he was a Scholar), and took his B.A. with first-class honours in the Natural Sciences Tripos of 1909. At Edinburgh he had been awarded the Vans Dunlop scholarship in 1905. Coming to London for the clinical course he soon made a name for himself at St. George's Hospital, and eventually won the Brackenbury prize in surgery, the William Brown scholarship, and the Herbert Allingham surgical scholarship. He qualified with the English Conjoint Diplomas in 1912, and, after holding house appointments, obtained the F.R.C.S.Eng. in 1914. During the last war he served in France with the temporary rank of Major R.A.M.C.(T.) in the surgical division of the 54th (London) General Hospital, B.E.F., and in England at the 4th London General Hospital.

Ewart had been surgical registrar at St. George's before his election to the visiting staff, and in due course became lecturer in operative and practical surgery. During the past 20 years he contributed a number of papers on abdominal disease to the *British Medical Journal* and the *British Journal of Surgery.* He leaves a widow (the younger daughter of the late Sir George Turner, K.C.B., consulting surgeon to St. George's), and one son and two daughters. Shooting was his favourite outdoor pursuit in middle life, but he had been a good long-distance runner and ran cross-country for Cambridge in 1909.

DR. ANDREW LOWRY MCCULLY, one of the oldest medical practitioners in Huddersfield, died on Sept. 17 in his 71st year. After a very distinguished career at Queen's College, Belfast, he graduated M.B., B.Ch., B.A.O., in 1897, with first place in the first-class honours list at the Old Royal University of Ireland. After settling in practice at Huddersfield he was appointed to the honorary staff of the Royal Infirmary as surgeon, and later medical officer in charge of the male venereal clinic, and on his retirement became consulting surgeon; he had also been obstetric consultant to the Huddersfield Corporation and lecturer for the Central Midwives Board. During the last war Dr. McCully served with a commission in the R.A.M.C. as medical officer of the 1/5th Duke of Wellington's Regiment and specialist surgeon at No. 56 C.C.S. He was a life member of the St. John Ambulance Association and had been corps surgeon to its Huddersfield Division. He joined the B.M.A. in 1906, was chairman of the Huddersfield Division in 1922, and president of the Yorkshire Branch in 1925-6. He was also a past-president of the Huddersfield Medical Society and the West Riding Irish Medical Society.

Medical Notes in Parliament

Medical Services for Miners: Committee's Report

Speaking during a debate on coal supply on Oct. 1, Mr. **Tom Smith** said an interdepartmental committee had been set up, with himself as chairman, to examine the suggestion in a recent White Paper on coal policy that there should be a medical service for the miners, not merely to deal with the certificates of those who wished to leave the industry, but to deal with rehabilitation and remedial treatment. The report of that committee had been prepared, and he would outline it to the House. It suggested that in each mining region there should be appointed a full-time medical officer, making 8 in the regions and with an additional 1 at headquarters, making 10 in all. At present there was only one full-time medical officer, who had done well but had had an impossible task of surveying 1,900 to 2,000 pits. Each regional officer would survey such things as first-aid treatment and ambulance services. Then there were the investigating and preventive measures concerning occupational diseases and fitness. Nystagmus was on the decline largely because of extra illumination. Of silicosis the House was to hear more in a few weeks. As a result of an inquiry in South Wales, it was to be called pneumoconiosis. In certain pits men suffered more on the average from carbuncles and boils than in other pits. That should be investigated. There was evidence of dermatitis—not limited to one district. The regional medical officer should be a man able to go down the pits and ascertain both causes and necessary preventive measures.

The interdepartmental committee recommended medical inspection of juveniles in accordance with the recommendations of the Forster Committee. At present it would be impossible to carry out the annual inspection of youths in pits up to the 19th year. The committee suggested that at the moment any youth entering the industry should be examined as to fitness for the work. The question of an annual inspection would be discussed with the Mineworkers' Federation. As regards fractures and allied injuries, it was proposed that where a miner, on medical advice, went for out-patient treatment the whole of his expenses should be paid on request. They desired so far as possible to use existing facilities for rehabilitation. They had the offer of one of the best places in Scotland. Where there were no facilities they aimed at rehabilitation centres. These existed at Mansfield, Wigan, and Lanark. They wished this rehabilitation work to be initiated by the Miners' Welfare Commission, whose chairman was convinced it would be pleased to do the work.

Mr. Smith said the figures for medical certificates showed that in one quarter just under 20,000 applications to leave the industry were based on these certificates. About 25% came from men at work and who had remained at work in the industry. Roughly half the cases were from four districts—South Wales and Monmouth, Durham, Lanark, and Lancashire and Cheshire. When a man presented a certificate with an application to leave the industry on medical grounds it was first scrutinized by the lay staff of the Ministry of Labour. If vague it was then submitted to a medical referee, whose decision was final. The interdepartmental committee suggested that certificates relating to miners should be lodged with the regional medical officer, who would scrutinize them and, if need be, get into contact with the man's own doctor or the medical referee. This might deter some doctors from lightly giving certificates. He believed that under the proposed medical service cases could be brought under review where men, while not ill, needed certain treatment to prevent them from having to stay away from work. The report generally would check wastage and prove of permanent benefit to those engaged in the mining industry. Mr. Smith said there was at present a gradual decrease in the accident rate in the mines. In the rush for increased production there must be no weakening in anything which made the mines safer.

The debate was adjourned.

Committee on Medical Schools

On Sept. 29 Sir E. **Graham-Little** asked the Minister of Health who were the members of the Interdepartmental Committee on Medical Schools, what was its reference, and whether the universities and medical licensing bodies were consulted about its composition and subjects of inquiry before the committee was formed. Mr. **Ernest Brown** pointed out that names were given in his reply on March 26 to Mr. Jewson. The reply to the second part of the question was "No."

Chiropodists for the Army.—Sir **James Grigg**, replying to Mr. J. Dugdale, on Sept. 29, said that in the early part of the war regimental foot orderlies were provided for field units and were thought adequate, especially in view of the increasing mechanization of the Army. In view, however, of experience, which suggested that more skilled treatment might be desirable, he was now considering the attachment of fully qualified chiropodists to field medical units.

Diphtheria Immunization.—The returns regarding diphtheria immunization from local authorities at Sept. 30, 1941, showed that between Jan. 1, 1940, and that date the number of notifications in England of diphtheria in children under 15 was approximately 51,700, and that approximately 2,380 of these children had received a course of immunization. In the same period the total number of children immunized under local authority arrangements in England was approximately 1,889,000. By the end of June, 1942, this number had increased to close on 3,000,000.

Price of Insulin.—On Oct. 1 Mr. **Tinker** alleged that hardship was caused to diabetic patients by the increased prices of insulin and needles. Mr. **Brown** replied that prices had increased, but having regard to the free provision of insulin and the necessary appliances for administering it under the National Health Insurance and Public Assistance schemes, he did not think there was a case for any special measures to prevent any increases warranted by the conditions of production.

The Services

Temp. Surg. Lieut. M. P. Martin, R.N.V.R., has been awarded the D.S.O., and Prob. Temp. Surg. Lieut. T. P. Storey, R.N.V.R., the D.S.C., for gallantry, daring, and skill in the combined attack on Dieppe, and Acting Temp. Surg. Cmdr. W. B. D. Miller, D.S.C., Prob. Temp. Surg. Lieut. J. G. C. Murray, and Temp. Surg. Lieut. R. Wadia, R.N.V.R., have been mentioned in dispatches.

Capts. L. G. Alexander and F. W. Hayter, R.C.A.M.C., have been awarded the M.C. in recognition of gallant and distinguished services in the combined attack on Dieppe, and Lieut.-Cols. K. A. Hunter and G. L. M. Smith and Capt. B. Brachman, R.C.A.M.C., have been mentioned in dispatches.

The King has awarded the R.N.V.R. Officers' Decoration to Acting Surg. Cmdrs. J. B. Hutchison and D. W. Bawtree, R.N.V.R.

The King has conferred the Efficiency Decoration of the Territorial Army on Col. (Acting Brigadier) D. S. Middleton; Lieut.-Col. J. R. McDonald, M.C.; Majors (Temp. Lieut.-Cols.) A. L. Crockford, M.C., F. N. Foster, E. G. R. Grant, P. J. Stokes, and M. L. Sutcliffe; Major (Acting Lieut.-Col.) K. S. Roden; Majors A. O'Hanlon and H. R. Paterson; and Capt. (Temp. Major) S. P. Wilson, R.A.M.C.(T.A.).

CASUALTIES IN THE MEDICAL SERVICES

The *University of London Gazette* dated July 24 contained a Roll of Honour. Among the medical officers listed there are three whose deaths have not been recorded in this column—namely, Surg. Lieut.-Cmdr. J. G. Slimon, R.N., Surg. Lieut. G. L. Cutts, R.N.V.R., and Lieut.-Col. J. J. Rooney, I.M.S., all of whom had been students of Guy's Hospital.

Surg. Lieut.-Cmdr. **James Gillespie Slimon** was killed by a train in Dec., 1939, while on leave. He graduated M.B., Ch.B. at the University of Glasgow in 1929. After holding the post of health officer at Kuala Lumpur in the Federated Malay States he entered the Royal Navy as surg. lieut. early in 1934 and was promoted in Jan., 1939.

Surg. Lieut. **George Lambert Cutts** died, following an operation, on June 6, 1940. He took the L.D.S. in 1914 and qualified M.R.C.S., L.R.C.P. in 1919, after which he was house-surgeon at Guy's and at the Queen's Hospital for Facial Injuries at Sidcup. He obtained the D.P.M. in 1925 and entered the L.C.C.'s Mental Hospitals Service, becoming successively A.M.O. at Bexley and at Long Grove, Epsom, and deputy medical superintendent of Friern Hospital. He rejoined the R.N.V.R., in which he served as surgeon-probationer in the war of 1914-18, soon after the outbreak of the present war.

Lieut.-Col. **John Joseph Rooney**, I.M.S., who died on April 5, 1941, was born on Jan. 27, 1890, and graduated M.B., B.Ch., B.A.O. of the National University of Ireland in 1920. He entered the I.M.S. soon afterwards, and was promoted capt. in 1923, major in 1929, and lieut.-col. in 1937. The earlier years of his service were spent at Lahore.

Wounded.—Capt. J. L. M. Whitbread, I.M.S.

Prisoners of War.—Col. R. D. Davy, M.C., Capt. D. Foskett, R.A.M.C., Capt. J. Gendle, R.A.M.C., Capt. R. G. Main, R.A.M.C., War Subs. Capt. H. J. McPherson, R.A.M.C., War Subs. Capt. A. P. Norman, R.A.M.C., Lieut. L. W. Ashton Rose, I.M.S., War Subs. Capt. N. C. Rogers, R.A.M.C., Lieut. A. W. B. Strahan, I.M.S., Capt. J. J. Woodward, I.M.S.

Missing.—Lieut. D. Christison, R.A.M.C. (*corrected announcement*), Surg. Lieut.-Cmdr. D. N. Ryalls, R.N.V.R.

Missing, Believed Prisoners of War.—Temp. Lieut.-Col. G. F. A. Condon, I.M.S., Temp. Major S. G. O'Neill, I.M.S.

Universities and Colleges

UNIVERSITY OF OXFORD

The King has approved that Arthur W. M. Ellis, M.D.Toronto, F.R.C.P.Lond., be appointed Regius Professor of Medicine in the University of Oxford on the retirement of Sir E. Farquhar Buzzard, Bt. Dr. Ellis until lately held a professorship of medicine in the University of London as Director of the Medical Unit of the London Hospital. He was appointed in March last by the Medical Research Council to a whole-time position on its scientific staff as Director of Research in Industrial Medicine.

UNIVERSITY OF CAMBRIDGE

The following candidates have been approved at the examination indicated:

Diploma in Medical Radiology and Electrology.—*Part II:* R. A. D. J. Bernhardt, A. B. Donald, H. R. Holmes, B. Kounine, A. Press, R. A. Williams, H. Wormald

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* substantial increases were recorded in the incidence of measles 358, scarlet fever 81, acute pneumonia 58, and dysentery 53 cases; for whooping-cough and diphtheria the notifications were 212 and 71 fewer.

Generally, the variation in the incidence within the counties was small. London and the south-eastern counties were responsible for the rise in scarlet fever. Lancashire, with 35 fewer cases, was the only county that showed a notable difference in the incidence of diphtheria; Yorks West Riding supplied the only local noteworthy change in the incidence of acute pneumonia, a rise of 37, and for whooping-cough 79 fewer cases.

The trend of measles to increase is not yet general throughout the country, being mainly in the northern section of the country; in the south the fall has not been checked. The largest increases during the week were recorded in Yorks West Riding 154, Leicestershire 92, Lancashire 83, and Warwickshire 61.

Owing to a duplication in the returns for enteric fever during the week ending Sept. 12 the published return was incorrect. The figure should have been 19 and not 37.

In *Scotland* the notifications of both measles and scarlet fever were 43 more than last week's total. While the higher incidence was due to a small general rise in the case of scarlet fever, the trend of measles was affected by only a few areas. The largest of the local increases in measles were those of the city of Aberdeen and the town of Paisley.

Dysentery

The number of cases of dysentery in England and Wales has increased for six consecutive weeks, and the 237 cases recorded during the week was the largest weekly total since the spring of 1938. No fresh outbreaks of any size occurred, and the increase of 53 cases this week was mainly due to an extension of the outbreaks which began last week in Essex and Yorks North Riding. In the former county notifications rose from 3 to 39, and in the latter from 8 to 25: 15 cases were reported from Hants, Droxford R.D., where the outbreak also began last week. In Oxfordshire and Norfolk, where the outbreaks have persisted for a month, there were 11 and 40 cases respectively during the week.

Small-pox in Fife

Small-pox has appeared in Fife. The cases were at first thought to be chicken-pox, and in view of this a warning has been issued by the Department of Health for Scotland to the local authorities that a thorough examination of all cases of chicken-pox should be made and any doubtful cases brought to the notice of the local medical officer of health. According to Press reports 10 cases have occurred in Methilhill and there have been 2 deaths.

Returns for the Week Ending October 3

The notifications of infectious diseases in England and Wales included the following: scarlet fever 2,423, whooping-cough 845, diphtheria 860, measles 3,801, acute pneumonia 508, cerebrospinal fever 61, acute poliomyelitis 33, dysentery 232, paratyphoid 5, typhoid 6.

No. 38

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Sept. 26.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1942					1941 (Corresponding Week)

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes paratyphoid A and B for Northern Ireland.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Medical News

The second Moynihan Memorial Lecture will be given by Sir Hugh Lett, Bt., ex-President of the Royal College of Surgeons of England, in the Riley-Smith Hall of the Students' Union building, University of Leeds, on Thursday, Oct. 29, at 3 p.m. Subject: "William Hey and After." Members of the medical profession are cordially invited to attend.

The first Bacot Memorial Lecture of the Lister Institute of Preventive Medicine, entitled "Bacot's Work on the Louse and Some of its Recent Developments," will be given by Prof. P. A. Buxton at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C 1, on Friday, Oct. 30, at 3 p.m

At the meeting of the Royal Medico-Psychological Association to be held at 11, Chandos Street, W., on Wednesday, Oct. 21, at 10.30 a.m., there will be a symposium on the incidence of tuberculosis and dysentery in mental hospitals.

A meeting of the South Yorkshire Section of the Institute of Chemistry will be held at Sheffield City Hall on Thursday, Oct. 22, at 2.45 p.m., when there will be a discussion on "The Chemist and Industrial Health," to be opened by Dr. F. S. Fowweather and Dr. M. W. Goldblatt.

A meeting of the Medico-Legal Society will be held at 26, Portland Place, W., on Thursday, Oct. 22, at 4.30 p.m., when Lieut.-Col. W. W. Mansfield will read a paper on "Disguise in Handwriting."

The next meeting of the North-Western Tuberculosis Society will be held at the Tuberculosis Offices, 352, Oxford Road, Manchester, on Thursday, Oct. 22, at 3 p.m., when Wing Cmdr. R. R. Trail will give an address on "Mass Miniature Radiography," illustrated by lantern slides.

The National Association of Maternity and Child Welfare Centres and for the Prevention of Infant Mortality is arranging a conference on mothercraft teaching and education for parenthood, to be held on Thursday, Oct. 22, at 2 p.m., at Carnegie House, 177, Piccadilly, W.

A special *x*-ray unit of the most modern type and costing £3,000 is to be sent to Leningrad by the Joint Committee for Soviet Aid, at Madame Maisky's request. The honour of presenting this unit to Leningrad has been given to the Civil Service Clerical Association, who have sent £6,000 to the Joint Committee for its mobile *x*-ray unit campaign.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent, London;* SECRETARY, *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Infra-red Radiation for Migraine

Dr. E. VENN CLAYDON writes: A patient of mine some time ago had a motor accident, one result of which was a marked increase in frequency and severity of attacks of migraine, which had dogged him for 20 years. I have recently been giving him infra-red radiation to the back of the neck for "fibrositis." The patient reports a renewed feeling of well-being, absence of attacks, and is able to do strenuous brain work with far less fatigue than formerly. Is this a known treatment for migraine and would it be safe to irradiate the head also?

Aspirin for Asthma

Dr. B. BANETH (Worthington) writes: In your issue of Sept. 19 there was an inquiry about the curative properties of aspirin in asthma. Aspirin is well known as an anti-allergic drug and was included in one of Prof. Lichtwitz's prescriptions for all kinds of allergic diseases, especially for asthma. There are quite a number of authors who consider that the well-known curative effects of aspirin are due to its anti-allergic properties only. In fact, to my knowledge aspirin alone is not frequently used as a remedy for asthma, as in some allergic patients it may act as a powerful allergin with severe consequences; I remember a very unpleasant and persistent urticaria after its use. But the same may happen with other drugs efficacious in asthma. The good effect of aspirin in an attack of asthma is no surprise for the student of allergy.

LETTERS, NOTES, ETC.

A Maternity Service Scheme

Dr. ROBERT SANDERSON writes: May I briefly call attention to a suggestion in Dame Louise McIlroy's address (Aug. 15, p. 184) that efficient voluntary maternity services should be subsidized. Take, for instance, the Brighton and Sussex Maternity and Women's Hospital. This is an old charity. William IV was the first subscriber. As to its efficiency the rough figures for the year 1941 are as follows: 1,400 deliveries (600 in hospital; 800 in the various districts of Brighton and Hove). There were 60 Caesarean sections. There was one maternal death. That this charity is in a chronic condition of insolvency is a reproach to the community and the country.

Diagnostic Sign in Ruptured Peptic Ulcer

Dr. V. E. BADCOCK, *M.C.* (Cornhill-on-Tweed), writes: In the *British Medical Journal* of Feb. 2, 1918, Prof. R. J. Willan drew attention to a helpful diagnostic sign in ruptured digestive ulcers. This sign, though not always present, does not appear to occur in any other acute abdominal condition and is particularly useful in an atypical case. It is of such diagnostic value that I feel it deserves to be better known than it is. The sign consists of a transverse ring or band of constriction across the abdomen at the level of the lower margin of the ribs and extending into the flanks at either side. It is just as if an invisible string was stretched tightly round the abdomen, dividing it into an upper and a lower portion. Prof. Willan described two cases of ruptured pyloric and gastric ulcers where this sign was prominent, and I have now seen it in my last three consecutive cases of ruptured duodenal ulcers.

MEDICINE 100 YEARS AGO

Extract from a leading article in the *Provincial Medical Journal* for October 15, 1842:

"To one of the most salubrious and delightful spots in England —the village of Malvern—has lately repaired one of the advocates of the water system, where he conducts an establishment upon the same plan as that of Priessnitz, in Germany; and, attracted by the *reports* of wonderful cures, thither flock 'the halt, the maimed, and the blind.' The same assurances of success are alike held out to all—to the gouty and well-fed alderman—to the poor, wan, and dejected creature, rapidly sinking beneath the strides of consumption—to the little infant, 'mewling and puking in the nurse's arms' —to him who has attained 'second childishness and mere oblivion' —to the unfortunate being who has never heard from his birth the sweet and varied sounds of nature, or whose heart has never been gladdened by the blessed light of day. That this water doctor performs many cures we do not for a moment doubt. But, on the other hand, we do not hesitate to affirm that the wholesale adoption of this remedy in indiscriminate cases has and will continue to be productive of the most serious and extensive mischief. And, in the first place, if we look to the instances in which hydropathy makes its most frequent cures, they will be found to be old chronic cases, for which the medical man previously in attendance recommended strong exercise, fresh air, bathing, nourishing and wholesome diet, with entire abstinence from all beverages of an exciting or inflammatory nature. But, the fact is, a physician finds it a very difficult thing to get his patients to do this. It causes too much trouble or expense, and they think that, in all probability, they shall recover without the adoption of such rigorous measures. The disease, however, is of a nature which will not admit of this; and so, if they do not get worse, at least they make no advances towards recovery. Then they hear of the *wonderful cures* of the water doctor, and away they go to his establishment. Here they are compelled to do that which was before recommended, for it is part of the system which builds its success solely upon a rigorous application. They rise early, walk the Malvern hills before breakfast, return home with the skin in a warm, healthy glow, eat sparingly, and drink nothing but water. Can anything be more beneficial than this to a person who has been a martyr to the gout, or to one who, from imprudence and intemperance, is frequently suffering from indigestion? Certainly not. But from its efficacy in one class of diseases is not to be assumed its efficacy in all."

⁎⁎ At the time the article from which the above extract is taken was published, hydropathy was very much in vogue. In the *Provincial Medical Journal* of September 24 and later, Dr. Charles Hastings, who was secretary of the Provincial Medical and Surgical Association (forerunner of the B.M.A.), was strong in his condemnation of the indiscriminate use of "the water cure," beginning one of his articles as follows: "It may well be doubted whether there is any country on the face of the earth in which quackery is so successfully followed as in rich and credulous England."

BRITISH MEDICAL JOURNAL

LONDON SATURDAY OCTOBER 24 1942

SOME ASPECTS OF CARDITIS*

BY

T. F. COTTON, M.D., C.M.McGill, F.R.C.P.

Physician to the National Heart Hospital

I shall describe in this paper certain symptoms and signs which have helped me in the management and treatment of patients, particularly children, with rheumatic heart disease. I have also some observations to make on prognosis, based on the after-history records of children over a 10-years period.

The symptom-complex of rheumatic fever does not present a uniform clinical picture. There is a monocyclic type with pyrexia, toxaemia, sweating, leucocytosis, and migrating polyarthritis; the heart may not be affected, and recovery is complete after a week or ten days of acute illness and three weeks of convalescence. In some these acute symptoms develop after a throat infection and two or three weeks of low-grade fever. There may be a second similar cycle of symptoms without cardiac involvement. Some have a persistent irregular temperature not rising above 100° or 101°, and there are rare cases with hyperpyrexia (Coburn, 1931).

Fever is the most constant of rheumatic phenomena. There may be no arthritis and no cardiac or other visceral manifestations of infection. Tachycardia, like pyrexia, is evidence of a general infection, and not necessarily due to the cardiac lesion; its relation to active carditis, except in advanced disease, may not be that of infection of heart muscle or valve, but the indirect effect of toxaemia on heart rate.

Temperature and Pulse

The temperature and pulse chart is an index of active rheumatic infection; it is not a record of the degree of cardiac damage. There are rare cases of hyperpyrexia in children, it is true, with severe carditis, and rapid heart action is common in heart failure; but high fever and a much-accelerated pulse with slight or no structural disease of the heart are not uncommonly associated. The case history of a boy of 6 illustrates this lack of parallelism between pulse rate and structural change. Three weeks after scarlet fever he developed pyrexia and a tachycardia of an unusually high rate with sinus rhythm; the heart was not enlarged, a systolic murmur audible over the mitral area was heard for the first time, and there was a profuse growth of haemolytic streptococci from septic tonsils. He was given sulphanilamide, and the temperature was normal in two days. He was discharged from hospital a week later with no abnormal heart signs. This was probably not a rheumatic infection, but will serve as an illustration of disturbed heart action of infective origin without structural disease. It is common knowledge that sino-auricular tachycardia is a reaction to infection; with a rise in temperature there is a corresponding increase in the pulse rate. When it is a reaction to heart failure there are always other signs of serious heart disease. In cardiac rheumatism active infection is more often the cause of a persistent rapid regular heart action at rest over a long period than myocardial insufficiency.

The sleeping pulse rate may be a guide to infection, but cannot be used to distinguish infection from heart failure as a cause of tachycardia, for in both conditions the sleeping pulse rate is raised, and approaches more closely the alert rate than in patients not actively infected or in failure. The pulse rate after exercise is increased by infection and by heart failure; this exaggerated reaction of heart rate may continue after the infection is quiescent and after recovery from heart failure. There are other factors involved in the response to effort which make the pulse rate after exercise an uncertain guide to infection or cardiac reserves. In early mitral stenosis, early aortic incompetence, and effort syndrome the rise in pulse rate after exercise may be the same, and is of little value in differential diagnosis. Tachycardia may be caused by nervous influences, infection, and heart failure; as an isolated sign it is unreliable evidence.

Dyspnoea

Dyspnoea after effort may be a symptom of infection, structural disease, debility, an abnormal nervous system, or some other quite different pathological process. Active rheumatic infection is usually absent when there is a valve lesion without enlargement of the heart. Few patients with either active or quiescent rheumatism complain of breathlessness at rest unless they have signs of heart failure. When these signs are absent, and the respiratory rate is raised, a heart lesion is not the cause.

When the heart with mitral or aortic disease is much enlarged, undue breathlessness after exercise, if there is no other known cause, is of cardiac origin. There is some difficulty in assessing this symptom when the valve lesion is not associated with an increase in the size of the heart; the myocardium has suffered slight injury, and carries an extra burden from the valve defects, but its reserve force is sufficient to meet the demands imposed on it by moderate exercise. Neurogenic influences may be the cause of the breathlessness, and not infrequently exercise tolerance is normal when these have been removed. The difficulties in dissociating breathlessness from the heart are much less when the valvular signs are of an equivocal nature; the systolic murmur as an isolated sign can be placed in this category.

Precordial pain is a common complaint of the patient with an inflammatory lesion of the heart; it is felt at rest, occurs more often after effort, and closely resembles the pain of effort syndrome. It is not anginal in character or distribution, and can easily be distinguished from the pleuropericardial pain of pericarditis by the cardiac signs. The precordial ache is a symptom of minor value in the diagnosis of structural disease.

Toxaemic Signs

There are signs of toxaemia which are not peculiar to a rheumatic infection but should nevertheless be treated with the greatest respect, for they serve as indirect evidence of structural change which may not be revealed by the heart signs. Pallor may be regarded as an important sign of infection in a rheumatic subject. A secondary anaemia of slight or moderate degree with a low-grade leucocytosis is the blood picture one expects to see in the active phases of carditis. It may develop rapidly, and the percentage of haemoglobin and

4268

the number of red corpuscles may reach extremely low levels, with anisocytosis and poikilocytosis, and with the colour index in most cases below unity

A girl aged 10 was admitted to hospital under my care 11 years ago in congestive failure, with moderate enlargement of the heart, aortic regurgitation, mitral stenosis, pericarditis, fever, and other signs of a rheumatic infection. The blood counts revealed a severe and progressive anaemia. The red blood cells fell to 2 millions, and the haemoglobin to 30%, with a colour index of 0.75; there were anisocytosis, poikilocytosis, and nucleated red cells. She was given liver by mouth in large quantities; she liked it and may owe her recovery to this strange taste. The red cell count rose to 5 millions and the haemoglobin to 90%. The tonsils were enucleated a year later. She now leads an active life, works in a munition factory, can walk four miles comfortably, and was married last year.

There may be rapid wasting, gradual but steady loss of weight, or failure to gain weight. This reaction of the body weight to infection will be influenced by the virulence of the infection or resistance to it, or such other factors as exercise, vomiting, diet, conditions of rest, and the age of the patient. The weight chart is a more accurate record of infection in children than in adults. The sedimentation rate is raised in active rheumatism, as in other infections, and may remain high when other signs of activity can no longer be detected. A very high rate is evidence of a severe infection. A low rate may be expected in the non-active phases of rheumatism. The rate falls with the onset of congestive failure, and is affected by the degree of anaemia; it is raised in thyrotoxicosis and in other diseases. It is a less reliable sign of infection in chorea than in other forms of rheumatism; it is comparable to the pulse rate, temperature, and weight charts in distinguishing between active and non-active carditis; it bears a close relation to the development and disappearance of nodules. Subcutaneous nodules and arthritis are characteristic phenomena of rheumatic activity, but they are also tissue reactions of rheumatoid arthritis, and cannot therefore always be accepted as unequivocal evidence of juvenile rheumatism. The absence of these signs does not exclude active infection.

Diagnosis of Active Carditis

I have so far described some important signs of rheumatic activity without reference to cardiac signs. It has been my object to show that it is possible, from a study of the reaction of the body as a whole to infection, to distinguish between the active and the quiescent phases of carditis. The correlation of these signs with those of structural disease of the heart is essential as a basis for prognosis and treatment. The diagnosis of active carditis from the cardiac signs alone is one not easily made. The disease may progress from recurring infection without any change in the quality of the endocardial murmurs. It is difficult to recognize reactivation of a chronic valve lesion from an acute infection, whether the signs are those of mitral stenosis, aortic incompetence, or mitral regurgitation. The development of a diastolic murmur not hitherto audible is an indication that inflammatory changes are taking place in the valve. The development of an apical systolic murmur has less pathological significance. It may be a sign of endocarditis, or a functional reaction to infection. The loud harsh murmur with slow heart rate is more often organic, but the soft bruit accompanying an overacting heart may be due to structural damage. The endocardial murmurs are unreliable signs of active carditis. The friction rub of pericarditis in the course of a rheumatic infection is unequivocal evidence of active structural damage to the myocardium. A wrong diagnosis of aortic incompetence is a not uncommon error, occasionally with grave consequences.

One expects to find some cardiac enlargement in acute rheumatic myocarditis; a close parallelism undoubtedly exists between acute rheumatic infection and an increase in the size of the heart. In a fair number of cases there is no enlargement, and other signs must be found before cardiac involvement can be diagnosed. Those who maintain that the heart is always enlarged when it has been attacked by rheumatism may have been misled by placing too much reliance on the uncertain palpable and percussion outline of an overacting heart. Even an *x*-ray examination has its limitations in determining slight changes in the shape and size of the heart.

The development of enlargement of the different chambers of the heart, of the aorta, and of the pulmonary artery can be determined by the radiological method, now regarded as part of a systematic examination of the cardiovascular system. Enlargement of the heart in the course of a rheumatic infection is a sign of myocardial injury; it is an early response to this infection, and is likely to be progressive when the rheumatic process is active. The size of the heart is related to the type of the initial infection. One expects to find the earliest increase in size, and the largest heart, among those who have had a severe attack of rheumatic fever. A mild infection may cause a valve lesion with little or no enlargement, and remain stationary in a long quiescent period of the disease. Enlargement is also a reaction to the extra load which the heart has to carry as a result of a valve defect. Changes in the shape and size of the auricles and ventricles may be a quick response to rapidly developing aortic regurgitation, or the gradual effect, from strain, of the slow sclerosing process of mitral stenosis. The degree of enlargement is a more reliable index of the virulence of the infection than is the valve deformity. Progressive enlargement is a more valuable sign of active infection than is a change in the character of the murmur

Heart-block

Electrocardiographic studies have demonstrated that in a large proportion of patients with active carditis there is a lengthening of the auriculo-ventricular conduction time. Cohn and Swift (1924) found that 84% of their cases with rheumatic heart disease showed some increase in the P–R interval. Keith's figures are approximately the same in those with carditis, and more than 50% in cases with chorea or arthritis without other signs of carditis (Keith, 1938). He concludes from his observations on the effect of atropine on the P–R interval that the mechanism responsible for the delay in conduction in all degrees up to complete heart-block is overstimulation of the vagus, and suggests that the exciting cause is the overactivity of the vagal nerve endings in the heart. Lengthened conduction may outlast all other manifestations of active infection for months. It is difficult to assess the significance of varying grades of heart-block in these circumstances. An arrhythmia of this type may be evidence of a localized pathological process in the region of the bundle, and a sign of active carditis; or it may be the residual effect of past rheumatism, a static situation not necessarily changing, like a murmur or enlargement of the heart. Transient partial heart-block can occur in association with vasovagal syncope; it may be a vagal effect without anatomical changes in the myocardium. The following two case records will illustrate how difficult it sometimes is to distinguish between active infection and residual myocardial damage on the evidence of heart-block.

Miss H., aged 20, had tonsillitis in July, 1939, and in August had well-developed symptoms and signs of rheumatic fever. In November there were no abnormal heart signs. In December the electrocardiogram showed heart-block with dropped beats, with no delay in conduction time after an exercise test and after atropine; the leucocytes were 11,200 per c.mm. and the sedimentation rate 5 mm. an hour. A diagnosis of active carditis was made on the evidence of heart-block and the history of recent rheumatism.

The other case is that of a young man aged 22. He had fainted in the past but had no return of this symptom for three years. His complaint at the time of examination was epigastric pain before meals. There was no history of rheumatism or sore throat. The heart was not enlarged and there were no murmurs. The electrocardiograms while in hospital showed partial heart-block with dropped beats and no delay in conduction after exercise and atropine; right axis deviation was present. There was no leucocytosis, and the sedimentation rate was not raised. Was heart-block in this case an isolated sign of active infection or residual damage from past infection? I did not think he had active carditis.

The development of auricular fibrillation is of great clinical importance, for it influences the course of rheumatic heart disease in the direction of heart failure and is therefore in close relation to the cause of death. It is a late manifestation of the rheumatic process, with an incidence of more than 40% among those who die, and the duration of life after its onset is less than three years in a large proportion of cases (De Graff and Lingg, 1935). Nutritional changes in the myocardium may be the cause of this disturbance of rhythm ; the part played by active infection as a causative factor in its production has not been demonstrated. There are some who hold the view that auricular fibrillation is sometimes an effect and not the cause of heart failure (Luten, 1936).

Interrelation of Heart Failure and Rheumatism

When we consider heart failure in relation to rheumatic infection there is a general recognition that these two conditions are interlocked. Acute or subacute rheumatic activity must be regarded as the chief cause of myocardial failure in rheumatic heart disease. Progressive enlargement is a constant feature of heart failure ; active infection may be responsible for progressive increase in size and failure. There are, among other contributory factors involved in these changes, a progressive valve lesion and auricular fibrillation ; both impose an extra burden on the heart and are closely linked with activity of infection. The heart failure of bacterial endocarditis is good evidence in support of the view that active infection plays a more important part in heart failure than mechanical strain.

Bacterial endocarditis is not evidence of rheumatic activity ; its relation to the phenomena of rheumatic disease is accidental (Coburn, 1931). It is a blood-stream infection which may present symptoms and signs easily distinguished from those of cardiac rheumatism. The temperature, pulse rate, and blood picture are not always distinguishing features of the two types of infection ; embolic phenomena may be absent, the fingers not clubbed, the spleen not palpable, and the blood sterile. In children, bacterial endocarditis is extremely rare, and consequently the difficulties of differential diagnosis do not often arise.

Prognosis of Carditis

I have some observations to make about prognosis, based on the after-history records of 200 boys with carditis, average age 11 years, over a 10-year period. These children were under my care in a special convalescent home, and the basis of treatment was rest in bed when there were symptoms or signs of active infection ; those without active infection were allowed to play games regulated to avoid undue breathlessness and over-fatigue. There are two consecutive groups of 100 ; in one group (Table I) the average stay in the home was four and a half months, and in the other (Table II), six months. The 200 cases are also dealt with as one group (Table III) by combining Tables I and II. They are classified as valve lesions in Tables I to III ; Table IV gives the degree of enlargement of cases in Table II. In Tables I to IV the numbers known to be alive or dead at the end of the tenth year are recorded.

Table I.—*Results of 100 Cases under Observation for 10 Years*

Disease	Cases	Living	Dead	Untraced
Mitral disease: systolic murmur	57	36 (63%)	18 (32%)	3
Mitral stenosis	23	8 (35%)	14 (61%)	1
Aortic regurgitation and mitral stenosis	14	7 (50%)	6 (43%)	1
Aortic regurgitation .	4	2 (50%)	2 (50%)	0
Non-valvular . .	2	1 (50%)	0	1
Total	100	54%	40%	6%

Table II—*Results of 100 Cases under Observation for 10 Years*

Disease	Cases	Living	Dead	Under Observation less than 10 Years
Mitral disease: systolic murmur	32	18 (56%)	8 (25%)	6
Mitral stenosis	34	16 (47%)	12 (35%)	6
Aortic regurgitation and mitral stenosis	24	9 (37%)	13 (54%)	2
Aortic regurgitation	6	3 (50%)	1 (17%)	2
Non-valvular	4	3 (75%)	0	1
Total	100	49%	34%	17%

Table III (*Tables I and II combined*)—*Results of 200 Cases under Observation for 10 Years*

Disease	Cases	Living	Dead	Untraced
Mitral disease: systolic murmur	89	54 (60%)	26 (29%)	9
Mitral stenosis	57	24 (42%)	26 (46%)	7
Aortic regurgitation and mitral stenosis	38	16 (42%)	19 (50%)	3
Aortic regurgitation ..	10	5 (50%)	3 (30%)	2
Non-valvular .. .	6	4 (66%)	0	2
Total	200	103 (52%)	74 (37%)	23 (11%)

Table IV.—*Degree of Enlargement*

Disease	Living						Dead						Grand Total
	Blank	0	+	++	+++	Total	Blank	0	+	++	+++	Total	
Mitral disease. systolic murmur . .	5	5	9	5		24	1	2	2	3		8	32
Mitral stenosis .. .	3	0	12	6	1	22	1		2	7	2	12	34
Aortic regurgitation and mitral stenosis	1	1	4	5		11	1	1	5	4	2	13	24
Aortic regurgitation .			4	1		5				1		1	6
Non-valvular . .			3	1		4							4
Total	9	6	32	18	1	66	3	3	9	15	4	34	100
		57%						35%					

Table V.—*Under Observation 1-5 Years and 5-10 Years*

Disease	Dead in 1–5 Years						Dead in 5–10 Years					Grand Total
	Blank	0	+	++	+++	Total	0	+	++	+++	Total	
Mitral disease: systolic murmur . ..	1		1	1		3	2	1	2		5	8
Mitral stenosis ..	1		2	4	2	9			3		3	12
Aortic regurgitation and mitral stenosis ..	1	1	4		2	8	1	1	4		6	14
Aortic regurgitation .				1		1						1
Non-valvular								3	1		4	4
Total	3	1	7	6	4	21	3	5	10		18	39

The figures in Table I show that 54% are living, 40% dead, and 6% untraced. In Table II 49% are living, 34% dead, and 17% untraced. In Table III 52% survive, 37% died, and 11% are untraced in this 10-year period.

In Table I 63% with mitral systolic murmurs are living and 32% dead ; 35% with mitral stenosis are living and 61% dead ; 50% with aortic regurgitation and mitral stenosis are living and 43% dead ; with aortic regurgitation alone 50% are living and 50% dead.

In Table II 56% are living and 25% dead in the systolic murmur group ; 47% with mitral stenosis are living and 35% dead ; with aortic regurgitation and mitral stenosis 37% are living and 54% dead ; with aortic regurgitation alone 50% are living and 17% dead.

Table III shows 60% living and 29% dead with mitral systolic murmurs ; 42% living and 46% dead with mitral stenosis ; 42% living and 50% dead with aortic regurgitation and mitral stenosis ; 50% living and 30% dead with aortic regurgitation.

In Table IV it will be seen that 57% with slight or no enlargement are living and 35% are dead at the end of 10 years.

Table V shows that 21 died within 5 years and 18 died in the second 5-year period.

Summary and Conclusions

Observations are made on the prognosis in carditis, based on the after-histories of 200 boys, average age 11 years.

Rather more than one-half of the children with carditis are alive and slightly more than one-third are dead 10 years after from 4½ to 6 months' treatment in a special convalescent home. The larger number of untraced cases in Table II (17% as against 6% in Table I) prevents one from concluding that the prognosis is more favourable when the stay in a convalescent home is increased from 4½ to 6 months.

Rather less than half of those who die within 10 years live longer than 5 years after treatment in a special convalescent home.

The death rate in children with mitral stenosis and aortic regurgitation is much higher than in those with mitral systolic murmurs, over a 10-year period.

Children with moderate or considerable enlargement of the heart are less likely to live 10 years than those with slight or no enlargement

REACTIONS FOLLOWING TRANSFUSIONS OF STORED BLOOD

BY

R. ARDEN JONES, M.B., B.S.

White Lodge E.M.S. Hospital, Newmarket

Two cases of blood transfusion reaction not due to incompatibility are here recorded. Though there is a lack of pathological data, they present such unusual features as to justify detailed clinical notes. The therapy employed in these cases invites criticism from many aspects. It is described rather fully, however, since the reaction to these measures involves interesting physiological considerations.

Case I

Woman aged 30. Six children. Rheumatic fever in June, 1940. Admitted for colpoperineorrhaphy. Haemoglobin 66%. Group A (II). Blood transfusion with Group O (IV) blood 4 days old, which was directly matched with the patient's serum and found to be suitable.

Nov. 19.—10.45 a.m.: Transfusion drip started. 11 a.m.: Complained of headache and vomited a little; chest felt tight. 11.30 a.m.: Felt cold and was a little shivery. At 12 noon, when 3/4 pint had been given, she complained of pain in the chest. The transfusion was stopped. Shortly afterwards colour was poor and pulse rapid and thready, 140 a minute. Resuscitation measures; omnopon gr. 1/3, heat cradle, and warm drinks were given, but vomiting became troublesome. Temperature rose to 102° at 2 p.m. and condition did not improve, the pulse remaining rapid and thready. The bed was blocked and rectal fluids were given. Coramine was administered repeatedly. Blood taken from a vein was sterile after 5 days' culture At 10 p.m. there was still no improvement. Lips cyanosed, eyes sunken, extremities icy, tongue dry, mentality clear, exposed veins empty, pulse almost imperceptible. Heart rate 140 regular: B.P. 40 systolic. Lungs clear. At 11.30 p.m intravenous saline was started, 2 pints being given rapidly.

Nov. 20—After the saline the B.P. rose to 75/55 at 12.25 a.m. and pulse was countable at 126. A third pint was run in more slowly, and at 4 a m. the B.P. had fallen to 60/45 and later to 50/35 One pint of plasma was then given rapidly (20 minutes), and at 5 a.m. the B.P. was 55/35. Further intravenous saline was given more slowly. Digoxin 0.5 mg. was injected intravenously, and D.O.C.A. 5 mg. was given Five hours later, at 10 a.m, the patient's condition was still that of profound collapse; T. 99°, P. 120, R. 20, B.P. 50/35. She was restless, sunken-eyed, and a little cyanosed; veins empty, a few crepitations at right base, no icterus. No urine had been passed since the transfusion reaction had occurred, nearly 24 hours previously Total intravenous fluid: 4 pints saline, 1 pint plasma. At 3.30 p m. 0.25 c.cm. pituitrin was given, and repeated in half an hour; the pulse, which had remained steady at 120 though poor in volume, fell to 100; but had risen to 120 by 6 p.m. Catheterization produced 7 oz. of highly coloured urine: albumin—moderate cloud; no blood, haemoglobin, or bile; pus, *B. coli*, and an occasional R.B.C. This urine may have been in the bladder since the transfusion was started. W.B.C. 23,000, R.B.C. 3,950,000, Hb 70%, blood urea 80 mg./100 c.cm. At 12 midnight, 24 hours after the intravenous saline had been started and over 36 hours since the reaction occurred, B.P. was still 55/35. T. 100°, P. 120, R. 28; hiccup, retching, very restless, neck veins not filled above the angle of Louis, lungs clear, no oedema. Eucortone had been given without improvement.

Nov. 21.—At 2.30 a.m. 0.25 c.cm. pituitrin was given, and repeated in half an hour as before; again the pulse fell promptly to 100. Respirations at this time had returned to 20. At 10 a.m., after a restless night, patient was slightly delirious. Hiccup persistent; P. 90, R. 30, B.P. 60/30. Slight dyspnoea, rhythm intermittent. Venous pulsation at root of neck but veins not filled above the level of the angle of Louis. Few basal rales. No oedema. Marked rigidity of all the limbs. Two pints of saline had been given in the previous 12 hours, making 11 pints in about 36 hours since the drip was started. Intravenous drip was discontinued. Urine, 4 oz., passed spontaneously at 6 a.m. (The first urine definitely secreted since the reaction had occurred—44 hours.) It contained albumin (heavy cloud); no blood or haemoglobin; pus cells but no casts in centrifugal deposit. Ephedrine gr. 1/2 was given by injection 3 times between 10.30 a.m. and 2 p.m., and thereafter gr. 1/4 every four hours. Urine, 6 oz., was passed spontaneously at 3 p.m. At 6 p.m there was definite clinical improvement Pulse had remained between 88 and 100 all day; B.P. 60/35, R. 24. At 12 p.m. pulse rate rose to 120, dyspnoea increased, patient became restless and delirious; B P. 75/40, R 30. Neck veins were not filled above the level of the angle of Louis. No oedema. Early failure was suspected, but ephedrine gr. 1/4 was continued 4-hourly, digoxin being given, 0.5 mg. b.d.

Nov. 22.—At 12 noon, 72 hours after the transfusion, patient was restless and wandering mentally. T 99°, P. 120, R. 30. Extensive herpes of lips, mouth sore, mucosa ulcerated, tongue dry and furred No icterus. Urine, 14 oz., was passed during the night. Casts, blood, and haemoglobin were absent During the day the pulse rate fell to 80 at 2 p m. and 66 at midnight, becoming grossly irregular. B.P., however, rose from 64/40 at 12 noon to 75/45 at 3 p.m. and 90/60 at 12 midnight. Definite congestive failure was now present, with 1½ in. of venous filling in the neck. Respirations 36–40; slight oedema of ankles and sacrum. The cardiac irregularity was considered to be due to auricular fibrillation in a fully digitalized patient. Ephedrine and digoxin were stopped. Urine passed during day measured 21 oz.

Nov. 23.—Diarrhoea with incontinence of faeces now occurred. Urine was being passed freely—65 oz. in 24 hours. Slow fibrillation continued, but signs of congestion had cleared. Hiccup was persistent. There was marked bruising of the skin at the site of injections and very slight icterus was thought to be present. Van den Bergh's reaction gave a very weak indirect positive. Blood urea 180 mg./100 c.cm. and urine urea 1.2% R.B.C. 4,610,000, Hb 80%, W.B C. 12,300, polys. 85%

Nov. 25.—Diarrhoea was still persistent though fluids alone were being given by mouth. Marked dehydration was present and fibrillation at 80 a minute continued. B.P 100/50 No icterus. At midnight dehydration was still pronounced, and patient was very reluctant to take fluids because of vomiting and ulceration of mouth and throat. I.V. saline was started.

Nov. 26 and 27.—Intravenous saline was continued, 16 pints being given in 48 hours. Urine passed during this period was 9½ pints in addition to that voided during a period of faecal incontinence. No sign of congestion or oedema developed, and on the 27th the pulse was regular at 90. Thereafter the patient recovered rapidly, and on the 29th B.P. was 115/75 and blood urea 50 mg./100 c.cm. Urine showed trace of albumin; pus cells and *B. coli* still present. No casts.

On Dec. 8 urea clearance was 70% of normal maximum clearance. Blood urea 36 mg./100 c.cm

Case II

Soldier aged 27. Admitted Dec 25, 1941, with gunshot wound of left thigh. During the week after admission repeated secondary haemorrhages occurred, which were treated by packing of the wound and compression bandages. Blood pressure ranged between 110/70 and 135/80. Temperature up to 100°.

On Jan. 1, 1942, R B.C. 2,750,000, W.B.C 26,000, polys 80%, Hb 50%. Group O (IV).

Jan 2—At 5.45 p.m. drip blood transfusion was started with Group O blood (citrated)—three days old—which had been directly matched with the patient's serum. No. 1 bottle (2/3 pint of whole blood) was given at a fast drip 60–100 a minute. At 6.10 p.m. severe rigor after about 1/3 pint Pulse 120. Blood drip reduced to 10–15 a minute. Adrenaline 5 minims and morphine gr. 1/4 given At 6.30 p.m. patient was shivery and complained of headache and pain in back of neck and chest. Vomited twice. No. 1 bottle was replaced by No. 2 bottle (though 1/2 pint still remained in No. 1), and this had run in by 8 p.m. without further reaction. Pulse remained at 120, but condition seemed better. The remainder of No 1 bottle was then given at 40–60 a minute and the transfusion was completed by about 9.30 p.m. without further incident. At 10 p.m.: Temperature 105°, pulse 160 and thready. Sweating profusely, vomiting at intervals and complaining of intense thirst Coramine was given and rectal saline started.

Jan. 3.—During the night he was restless and slept for short intervals only. He took large quantities of water by mouth and vomited repeatedly. Pulse fell to 100 at 5 a m.; volume improved slightly. Temperature 99° From 5 a.m. pulse rose gradually; at 9 a m. he was pale, grey, and the pulse was imperceptible. He was again given coramine. At 10 a.m.: T. 97°, P. 104, R. 28; pale and restless; pulse volume poor; B P. 50 systolic; no dehydration;

no icterus. There had been no bleeding from the wound. At 11.30 a.m. 4 oz. of urine was passed spontaneously, the first since onset of reaction 18 hours previously (16 oz. had been passed 2½ hours before the reaction occurred); S.G. 1020, trace of albumin; no blood or haemoglobin. At 2.30 p.m. condition unchanged; P. 120, B.P. 50 systolic, R. 26. Intravenous saline with 5% glucose started by a drip adjusted to 40 a minute. At 6 p.m. patient was still restless and was vomiting; T. 99°, P. 130, R. 36, B.P. 62/40. A little over a pint of saline had been given, but no further urine had been passed, though 85 oz. of fluid had been taken by mouth in the preceding 12 hours and only 18 oz. had been vomited. There was no sign of congestion despite slight dyspnoea and raised respiration rate. At 10 p.m. his condition had deteriorated further: B.P. 60/40, T. 98°, P. 140, R. 40. 36 oz. of I.V. saline had been absorbed since the onset. 1 pint of fresh blood (group IV) was then substituted for the saline and run in slowly at 10 drops a minute.

Jan 4.—During the night pulse fell to 106 though respirations remained at 40. Patient was delirious at times and very restless. Temperature 99°. At 4 a.m. (34 hours since onset of reaction) 14 oz. of urine passed. It contained albumin (moderate cloud); no haemoglobin; no R.B.C.s, occasional W.B.C.; fair number of granular casts. At 10 a.m. 1 pint of blood had been absorbed and the remainder of the original 2 pints of saline was given slowly. Intake for preceding 12 hours, 60 oz. by mouth; urine 14 oz.; vomit *nil*. Patient was restless and coughing repeatedly. No icterus. T. 98°, P. 120, R. 44, B.P. 80/60. At 12 noon a second pint of fresh blood was given at 15 drops a minute. At 4.30 p.m. B.P. 80/60; P. at 120 all day; R. 36-40; T. 99°. General condition slightly improved. Patient, however, looked extremely ill, pale, sunken-eyed, but not dehydrated. Persistent cough. Intake (12 hours) 58 oz.; output of urine 16 oz. At 10 p.m. signs of consolidation were detected at the right base and sulphapyridine was given. At 12 midnight the second pint of fresh blood had been absorbed and the drip was continued at 10 a minute with saline.

Jan. 5.—At 10 a.m.—64 hours since onset of reaction—intravenous saline was discontinued. Only 10 oz. had been given in the preceding 10 hours. (Total fluid given by this route in 44 hours was 2 pints blood and 2½ pints saline.) Intake by mouth 36 oz., urine output 19 oz. T. 100°, P. 116, R. 40, B.P. 105/70. Radiograph of chest confirmed consolidation at right base. Blood urea 130 mg./100 c.cm. W.B.C. 38,000—85% polys. Urine contained albumin and casts but no red cells or haemoglobin. At 5 p.m., T. 100°, P. 120, R. 40. Congestive cardiac failure was present with 2 in. of venous filling in the neck. B.P. 115/80. Liver just palpable; slight oedema. Extensive herpes of lips. Dry sore tongue, heavily furred. No icterus. Purulent sputum and signs of pneumonia at right base also noted. Diuresis had begun during the day, and 82 oz. of urine was passed during the 12 hours.

Jan 6.—The patient's condition had materially improved. Signs of congestion were fewer and diuresis continued. Sulphapyridine was continued up to a total of 25 g. Blood urea 130 mg./100 c.cm.

The patient thereafter proceeded to make an uneventful recovery. On Jan. 12 blood urea was 45 mg./100 c.cm., and concentration of urea in morning specimen of urine 1.7%. On Jan. 14 Hb 80%, R.B.C 4,000,000; urine contained no albumin, and no abnormal elements were present in the deposit.

Comment

The similarity of the reaction in these two cases is striking, and that they are unusual has been confirmed by both Prof. Arthur Ellis and Dr. Janet Vaughan (personal communications), who agree that intravascular haemolysis could be excluded. The dominant features were the absence of intravascular haemolysis, the extremely grave condition of the patients for over a week, and the sustained low blood pressure, being no higher than 60 mm. Hg systolic for over 48 hours in Case I. Marked nitrogen retention and a phase of congestive cardiac failure occurred in both cases.

Neither patient had been transfused before. The compatibility of the blood used in each case would seem to be satisfactory. The grouping of donors and recipients' blood was repeated and confirmed, and direct matching of serum from the recipients and cells from the donors was carried out in each case. Moreover, icterus and haemoglobinuria, though anticipated and looked for, were absent. The suspicion of slight jaundice on the fifth day in Case I could not be attributed to primary haemolysis of the transfused blood, and it was noted that there was extensive bruising at the site of repeated subcutaneous injections.

In both cases the blood given was less than five days old. It had been stored in a refrigerator at 4° to 8° C., and was macroscopically normal. No trace of haemolysis was visible above the surface of the sedimented cells, and microscopically the erythrocytes were healthy in appearance. In warming the blood care was taken that it was not exposed to an injurious temperature.

Infection of the blood cannot be excluded. Contamination of a batch of blood taken at another time did occur, though the infected specimens were in every case grossly abnormal macroscopically in under five days, and some 20 samples which were cultured and which appeared normal to the naked eye were not infected. That heavily infected blood may appear normal macroscopically is, however, recognized. Clearly, infection of the transfused blood is a possibility in both these cases, and the negative blood culture from Case I shortly after the onset of the reaction does not exclude this accident.

The nature of these reactions is uncertain, but an increase in the total vascular bed consequent upon a loss of peripheral vascular tone, with or without subsequent loss of fluid into the tissues, can reasonably be assumed. That this resulted from some substance in the transfused blood is probable, but whether this was a toxin of bacterial or other origin or an allergen is speculative. The prolonged duration of the collapse argues against a true anaphylactic reaction. The pneumonia in Case II suggests infection (Whitby, 1942), as does the leucocytosis.

The nitrogen retention would seem to have been the direct result of a loss of glomerular filtration during the period of hypotension, as with the recovery of the blood pressure diuresis set in. Hypertension did not occur at any time.

In the case of the milder reaction (Case II) more protein-containing fluid was given than in Case I, though in the latter excessive quantities of saline had been infused. In both cases a period of congestive cardiac failure occurred coincidently with the recovery of the blood pressure, but *some time* after the intravenous infusions had been stopped. This venous congestion, not directly attributable to a rapid overloading of the circulation with infused fluids, might be explained by the recovery of peripheral vascular tone on a blood volume which had been artificially raised above its normal level. The increased blood volume had previously been accommodated by an increased vascular bed. It is suggested that this occasionally occurs in cases of traumatic shock treated early by transfusion.

The infusion of large quantities of saline and proteinous fluid would seem to be irrational, and was clearly excessive in these cases. Though it certainly aided the circulation by maintaining the blood volume above its normal level it probably made subsequent congestion inevitable. For this reason saline was used in preference to plasma in Case I, but the danger of precipitating pulmonary oedema was thereby obviously increased.

Adrenal cortical extracts were given in Case I as an acute adrenal lesion was feared, but the response to this measure was negligible. Transitory response to pituitrin in Case I appeared definite. Ephedrine, though given in large doses by injection, could not definitely be shown to produce the desired effect, the blood pressure falling almost to its earlier level during its administration. Coramine was not effective. Veritol and other vascular stimulants were not tried.

Pituitrin is known to increase capillary vascular tone. Wenckebach (1932), in studying the effect of pituitrin on the cardiovascular phenomena of beriberi, showed clinically that this drug acts principally by constricting the capillaries. Its use, therefore, in cases such as those here reported would seem to be rational. It was not persisted with, however, for fear of embarrassing the cardiac circulation and so precipitating a fatal issue.

Summary

Two unusual cases of blood transfusion reaction, not due to incompatibility, are recorded, together with a brief commentary. Profound and sustained collapse with subsequent nitrogen retention and congestive cardiac failure occurred in both instances.

I wish to express my thanks to Mr. J. Preston Maxwell and Mr. John E. Rowlands for allowing me to report these reactions in their patients; to Prof. Arthur Ellis, Dr. Janet Vaughan, and Prof Ryle for personal communications; and to Dr. A. Morton Gill and Dr. Leo Pollak for helpful advice and criticism.

BAGASSOSIS

AN INDUSTRIAL LUNG DISEASE

BY

L. I. M. CASTLEDEN, M.D., M.R.C.P.

AND

J. L. HAMILTON-PATERSON, M.D.

(With Special Plate)

Bagasse is the term applied to broken sugar-cane after the sugar has been extracted. This formerly waste product of the sugar-cane industry is now employed in the manufacture of board which, besides being an easily worked and durable material, has the property of insulating any cavity lined with it against sound and temperature changes. The many possible applications of these properties in building are obvious. At the present time the material is in demand for war purposes. The bagasse arrives at the board-making factory in open bales, which are then "broken"—i.e., the raw material is further crushed into small fragments. When manufacture was first started in England the bale-breaking was carried out under water. The process was slow, however, and about two years ago machinery was devised for breaking the bales in a dry state that proved to be much more rapid but gave rise to a great deal of dust, some very finely divided, in the air near the machinery.

Bagasse, which is largely composed of fibre, contains about 1% of protein and 5 to 7% of silica. Some of its cellulose content is said to be present in a crystalline form. The rest of the processes through which the bagasse goes are wet, an initial washing probably removing all the protein content, until the finished board is dried in a heated press at a temperature of 200° F. in the centre of the board, which would destroy any remaining protein. It is then cut and trimmed by circular saws, a process which again gives rise to a small quantity of dust containing silica but no protein.

Directly after the installation of the dry bale-breaking machinery, cases of respiratory illness began to appear among the workers engaged in this part of the process—namely, the labourers who fed the bales into the machine and the engineer who supervised its construction and running. No cases of respiratory trouble had previously occurred in the factory. Those workers who are engaged in the cutting and trimming of the finished boards are never affected. As soon as it was realized that the dust liberated at the initial stage of manufacture was injurious, measures were taken to suppress it. These consisted of a water spray and a suction draught applied to the site of its generation, and since the application of them no further cases of illness have occurred among the workers. The clinical features of four of these cases seen and the investigations made upon them are as follows:

Case I

A labourer at the factory aged 19, this patient had always enjoyed good health. There was no history of any chest trouble or of tuberculosis in himself or his family. He began work in the factory in Feb., 1941, and was exposed to bagasse dust as he fed bales into the breaking-machine. Since the end of March, 1941, six weeks before admission to hospital on May 4, he had had increasing shortness of breath and for four weeks a cough with scanty sputum that was sometimes blood-stained. He had been unable to work for ten days before admission.

On examination he was very dyspnoeic at rest, being hardly able to speak, but had only moderate cyanosis There was occasional cough with a scanty, frothy, sticky, muco-purulent sputum which was sometimes streaked with bood. There was no clubbing. The heart was normal and the blood pressure 140/60. The chest showed poor movement, with rather less on the right side than on the left. The trachea was central. The percussion note was impaired, with distant bronchial breathing in small areas at both bases. Vocal fremitus and vocal resonance were diminished at the right base. A few rales were present at the right base and scattered fine crepitations in all other areas. The abdomen, central nervous system, and urine were normal. A radiograph taken on May 5 (Plate, Fig. 1) suggested bilateral bronchopneumonia of influenzal type.

Progress—The temperature, which was 100.6° on admission, fell to normal in two days, at which it remained until the ninth day, when remittent fever began, lasting one week. The rest of the course of the illness was afebrile. The pulse rate varied between 104 and 144 and the respirations from 24 to 48 a minute until the patient was well. Cyanosis with extreme dyspnoea persisted for three weeks, then both gradually subsided over the next four weeks A radiograph taken on June 19 showed an increase in the area of consolidation (Fig. 2). The dyspnoea, which never had an asthmatic quality, was markedly relieved by oxygen, which was kept up continuously by nasal catheter for 51 days. Sulphapyridine appeared to have no influence on the course of the disease. Signs of patchy consolidation persisted in both lower lobes, varying in location and intensity for 7½ weeks, with rales frequently in other areas also. Finally the dyspnoea gradually ceased, oxygen was dispensed with for increasingly longer intervals, the chest began to clear by July 5 (Fig. 3), and the patient became subjectively well. He was followed up as an out-patient, remaining symptom-free, with further resolution of the lung lesions (Fig. 4), and five to six months after this last film was taken was admitted to the Navy.

The sputum was always scanty, muco-purulent, and at times blood-stained. The bacterial flora was varied, containing *M catarrhalis, Str. viridans*, and fusiform bacilli. *Staph. aureus* was grown on one occasion, and on another pneumococcus Type 14. Tubercle bacilli were not found. The cells in the sputum were epithelial, polymorphonuclear, and lymphocytic Eosinophils were never present

The blood count on admission was: red cells, 4,610,000 per c.mm.; haemoglobin 78%; colour index 0.87; leucocytes, 11,300 per c.mm.—neutrophils 83%, lymphocytes 14%, monocytes 3%, and no eosinophil cells. Subsequent white counts gave 9,200 and 9,300 cells, with normal differential counts containing 3% and 1% of eosinophils respectively.

Case II

This patient, an engineer aged 37 who had previously enjoyed good health except for an attack of influenza in 1936, had no history of chest illness in himself or his family, none of whom had had tuberculosis in any form. In March, 1939, he started work in the factory, where from Aug., 1939, to June, 1940, he was in intermittent contact with bagasse dust. From June, 1940, to Sept., 1940, he was in continuous intimate contact with the dust, superintending the construction and running of machines for the dry crushing process. In Sept., 1940, he became ill with a chest complaint which was called pneumonia, and was off work for 10 weeks. The symptoms of his illness corresponded to those of Case I—namely, shortness of breath, cough, and scanty sputum. During convalescence he was sent by his doctor, under whose care he had remained at home, to see the Tuberculosis Officer, who reported no P.T. In Nov., 1940, he returned to work, and in December began to be short of breath again. This shortness of breath rapidly and steadily increased so that by Jan., 1941, he was out of breath at the least exertion and was able to work one day only in every three. On Jan. 17, 1941, he attended hospital as an out-patient On examination there was seen to be early clubbing of the fingers. The chest was kyphotic, with many fine rales in all areas of both lungs anteriorly and at both bases Physical examination was otherwise normal. A radiograph taken on Jan. 18 (Fig. 5) showed a few apical scars and a little fibrosis in the right midzone. By May, 1941, his shortness of breath was extreme and painful, and he would collapse in the street from walking slowly. In one of these attacks of collapse he was admitted to another hospital, where a radiograph was thought to reveal bilateral apical tuberculosis. After this he continued at home with troublesome shortness of breath until he was admitted to hospital on Nov. 22, 1941.

On examination there was marked dyspnoea at rest with orthopnoea but no cyanosis. Clubbing of the fingers was present. The spine was kyphotic and the thorax rigid, and upon comment being made on this the patient stated that he had been becoming more "round-shouldered" since Jan., 1941 The trachea was central and the percussion note impaired at the left apex both in front and behind, with bronchial breathing and bronchophony. Crepitations were present throughout all areas of the left lung and at the right apex. The heart was

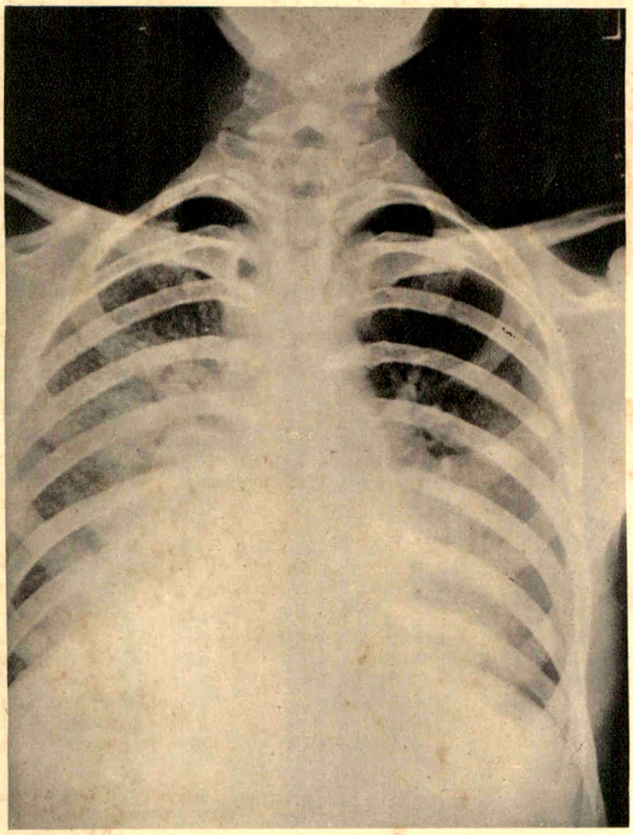

FIG. 1.—Case I (May 5, 1941). Bilateral basal mottling of bronchopneumonic type with enlarged right hilum gland.

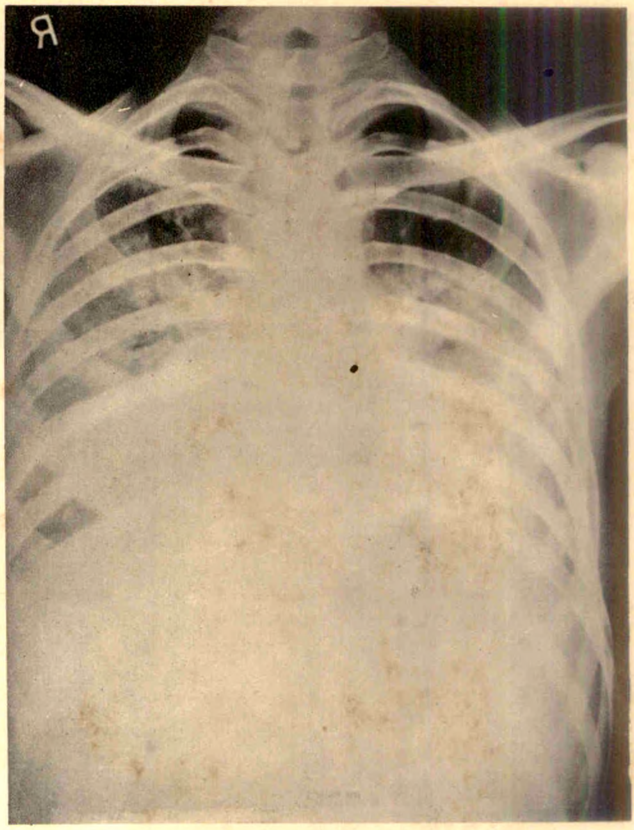

FIG. 2.—Case I (June 19, 1941). Extension of the lesions.

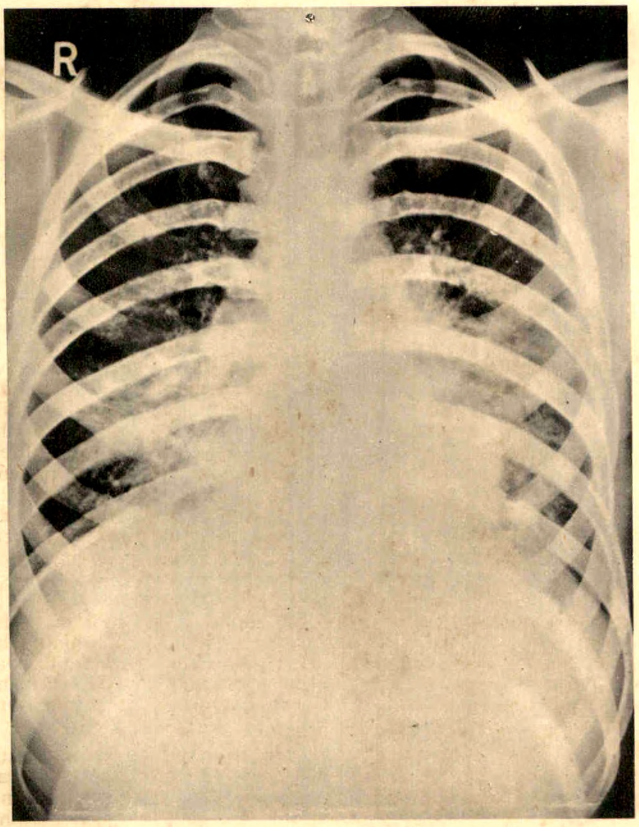

FIG. 3.—Case I (July 5, 1941). Resolution starting.

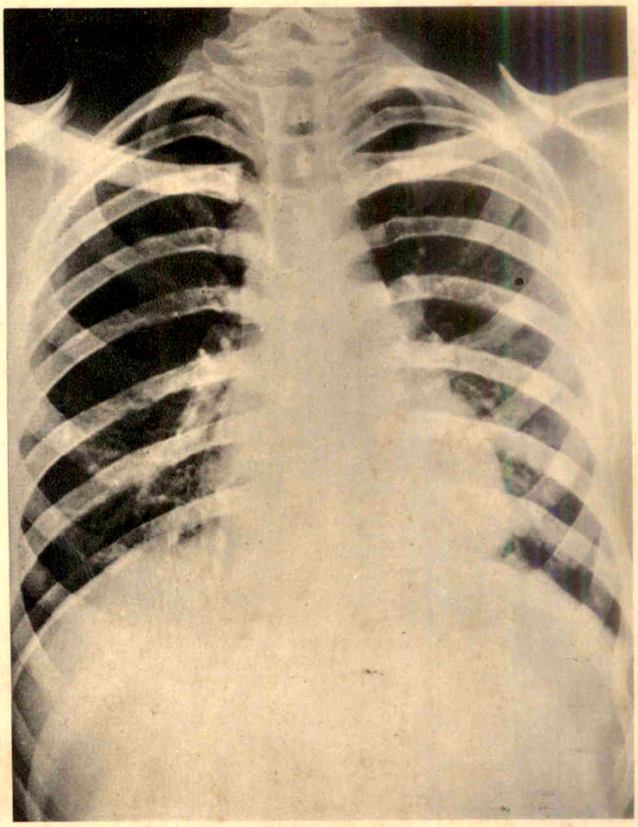

FIG. 4.—Case I (Aug. 29, 1941). Complete resolution of lung lesions except for a little basal striation.

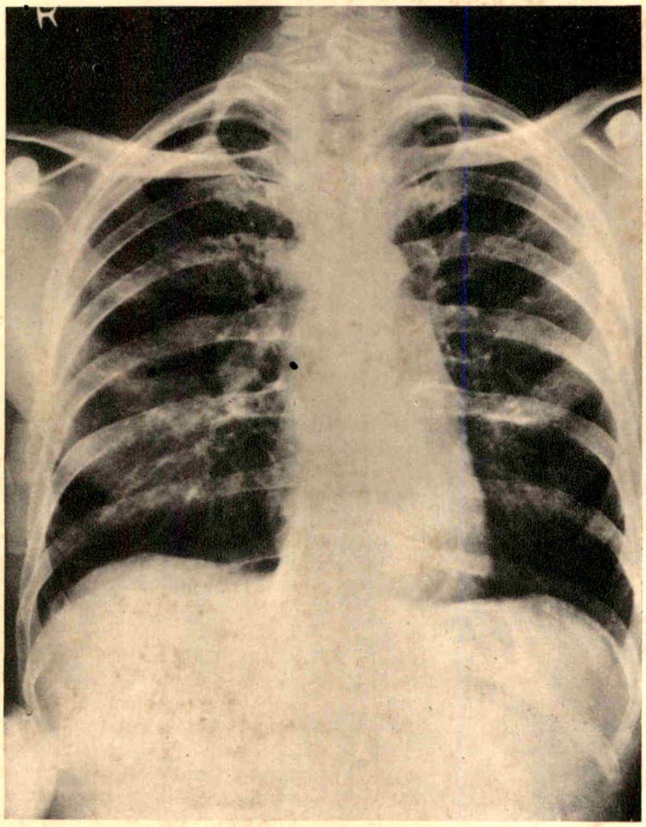

FIG. 5.—Case II (Jan. 18, 1941). A few apical scars and a little fibrosis in the right midzone.

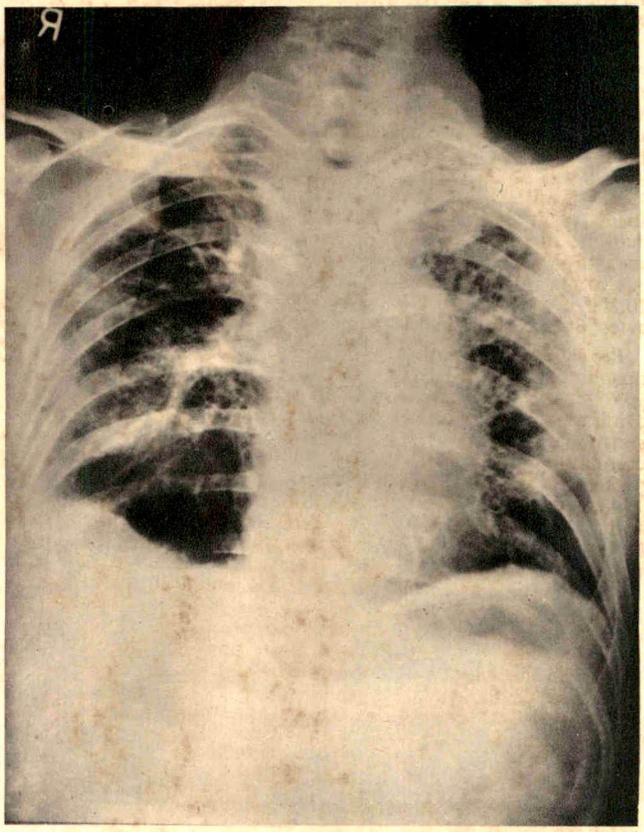

FIG. 6.—Case II (Dec. 5, 1941). Wide upper mediastinal shadow; irregularity of contour of right diaphragm with pleural thickening in costophrenic angle; streaky opacities of fibrotic appearance in both lungs.

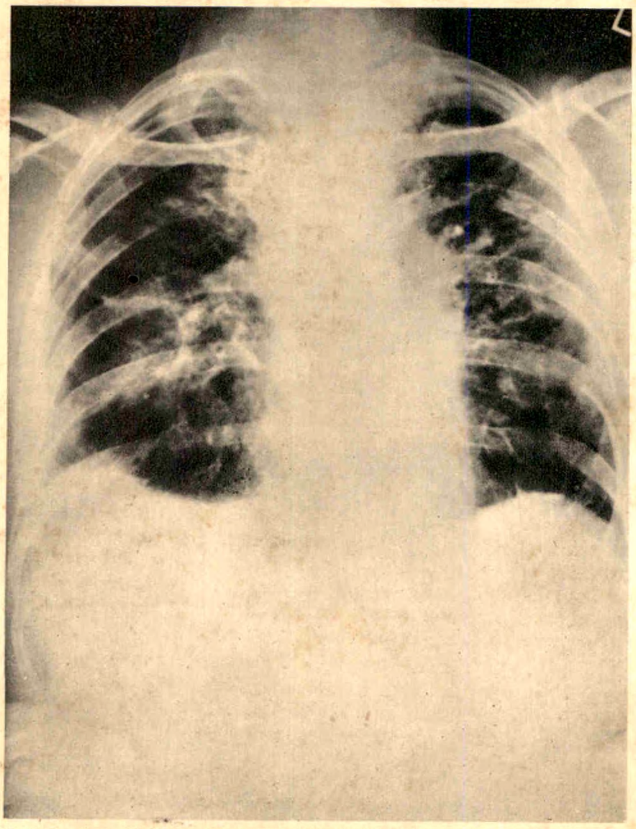

FIG. 7.—Case II (June 24, 1942). No radiological evidence of resolution.

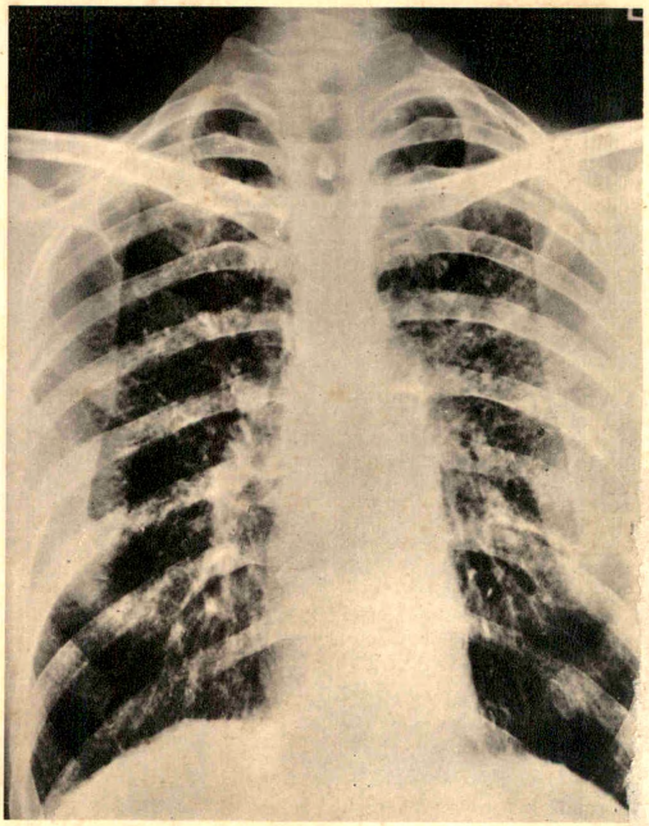

FIG. 8.—Case IV (June 15, 1942). General streaky opacity throughout both lungs.

normal and the blood pressure 110/70. The abdomen, central nervous system, and urine were normal. There were no signs of congestive cardiac failure.

The sputum was mucoid, viscid, scanty, but never blood-stained. The cells in it were polymorphonuclears and lymphocytes. Eosinophils were not seen. The bacterial flora was mixed, containing the usual mouth organisms, with occasionally haemolytic streptococci and pneumococcus Type 23. Tubercle bacilli were not found on repeated search. A special search was made for yeasts, moulds, and fungi, but none were seen. Radiographs taken on Dec. 5 (Fig. 6) showed appearances very much like bilateral pulmonary tuberculosis, and that the lung lesions had advanced since he had been seen as an out-patient. A blood count showed: red cells, 4,590,000 per c.mm.; haemoglobin 94%; colour index, 1.02; leucocytes, 10,200 per c.mm.—polymorphs 51%, lymphocytes 32%, monocytes 6%, eosinophils 11%.

Progress.—The patient was afebrile throughout his stay in hospital except for very occasional temperatures of 99° to 99.6°. The pulse rate was 80 to 100 and respirations 20 to 24 a minute. The dyspnoea gradually decreased and the signs of consolidation in the left upper lobe disappeared, but rales and crepitations persisted throughout the left lung, and were usually present at the right apex or base. On discharge on Feb. 15, 1942, he was able to get about with less dyspnoea than formerly, and has attended as an out-patient since with decreasing dyspnoea but with increasing kyphosis and occasional dragging pain in the lower part of his chest on the left side. He continues to attend as an out-patient and is unable to work. Radiographs taken on Feb. 2, March 16, and June 24, 1942 (Fig. 7) are all identical. They show some resolution of left upper zone shadows between Dec. 5, 1941, and Feb. 6, 1942; but thereafter the widening of the mediastinal shadow in the upper part, the peculiar streaky opacities in both lung fields, and the peripheral basal pleural thickening have remained unchanged.

Case III

A labourer aged 40 attended as an out-patient, complaining of shortness of breath. He was working at the same machine as Case I, and after one month at the job began to be short of breath, had a cough with scanty sputum and chest pains. He was off work intermittently, and was finally transferred to an open-air part of the factory, since when he has had less cough but his shortness of breath has continued. He had had no previous chest trouble. There was no history of tuberculosis in his family.

On examination he was slightly dyspnoeic. There was no clubbing of the fingers. The chest movements were poor but equal, with impairment of the percussion note at the left base and in the left axilla. The breath sounds were diminished in these areas. There were no added sounds. The heart, abdomen, and central nervous system were normal. The blood pressure was 140/90. The blood count was: red cells, 4,560,000 per c.mm.; haemoglobin, 100%; colour index, 1.1; leucocytes, 3,000 per c.mm.—neutrophils 43%, eosinophils 3%, basophils 1%, lymphocytes 49%, monocytes 4%. A radiograph of his chest demonstrated no lung lesion.

Case IV

A labourer aged 44 attended as an out-patient, complaining of shortness of breath. Sixteen months ago he had begun work at the factory and was exposed to bagasse dust when feeding the bale-breaker. A year ago he began to be short of breath and to have a cough without any sputum. He was able to work for increasingly shorter times before difficulties with his breath compelled him to stop. Finally he could manage to work only one to three days in each week. He was then transferred to outdoor work, since when he had been getting better but was still very short of breath on exertion.

He had had pneumonia in 1914, from which he had made a good recovery, but had had no other illnesses. There was no family history of tuberculosis. On examination there was moderate cyanosis with dyspnoea at rest. There was no clubbing of the fingers. The percussion note was impaired at the right apex, with diminution of the breath sounds in this area and at the right base. The breath sounds were normal in character. A few rhonchi were present throughout both lungs. The heart, abdomen, and central nervous system were normal. The blood pressure was 110/70. The blood count was: red cells, 5,010,000 per c.mm.; haemoglobin, 108%; colour index, 1.08; leucocytes, 6,600 per c.mm.—neutrophils 55%, eosinophils 1%, lymphocytes 40%, monocytes 4%. A radiograph taken on June 15, 1942, showed a general streaky opacity throughout both lungs (Fig. 8).

Discussion

The clinical appearance of these patients suggests an acute inflammatory lung disease with urgent and extreme dyspnoea as the presenting symptom but with little or no febrile reaction. On admission Case I was thought to be suffering from bilateral bronchopneumonia, which appeared to be of the influenzal type, but there was no epidemic of influenza at the time and he had already been ill for six weeks before admission—two facts which were against this diagnosis. There had been no case of psittacosis in this country for several years, and he had had no contact with birds of the parrot species. The alternative seemed to be that the lesion was tuberculous or was a form of chronic pneumonia (Scadding, 1936). The radiological appearances were more those of an influenzal bronchopneumonia than of a tuberculous lesion: tubercle bacilli were never recovered from the sputum, and he had long periods when he was afebrile with persistence of his symptoms and signs, so that some form of chronic pneumonia seemed the most likely diagnosis; but here again the absence of pyrexia was difficult to explain. His history of being employed in a dusty occupation naturally led to further inquiry concerning this. He said that some of his workmates had complained of cough and shortness of breath; but the medical officer of the works stated that although several of the employees had had respiratory illnesses about that time he had no reason then to connect them with the work upon which the men were engaged. The eventual complete resolution of the lesions with the return of the patient to normal health seemed to indicate their inflammatory nature, the aetiology of which remained obscure. There the matter rested until Case II was admitted to hospital. He also had the presenting symptom of extreme dyspnoea, and on his physical signs and the radiological appearances was thought at first to be suffering from bilateral active tuberculosis, but tubercle bacilli were persistently absent from his sputum, and he also had long periods when he was afebrile in spite of the apparent activity of the disease. The presence of persistent extreme dyspnoea called to mind the appearance of Case I, and upon inquiry it was found that his occupation, which was given as that of an engineer, concealed the fact that he had not only been working in the same factory as Case I but also had been exposed to the same dust. Contact was then made with the Factory Department of the Ministry of Labour and National Service to ascertain if workers at this factory were subject to an industrial dust disease. Dr. E. M. Middleton, one of the medical inspectors, kindly came to see Case II in consultation; he said that the illness was similar to others which had occurred in workers at the factory, and was probably bagasscosis (or, as we prefer to call it, "bagassosis"), a disease first recorded by Jamison and Hopkins (1941). These writers described an acute illness occurring in a young negro labourer who had been employed unloading bagasse at a board-making factory in America. His work was very dusty, and his illness was characterized by marked dyspnoea, cough with scanty sputum which was sometimes blood-stained, and physical signs and radiological appearances suggestive of bilateral bronchopneumonia. He made a complete recovery, and the lung lesions, after passing through a stage of "miliary mottling" radiologically, resolved, the clinical and *x*-ray appearances described being parallel to those of Case I.

Jamison and Hopkins were able to grow a fungus on two occasions from a concentrate of a 24-hour specimen of sputum in their case, and advanced the view that it was a fungous disease of the lungs. They reported their case at a medical meeting, at which Fasting (1941) stated that he had seen three or four similar cases, which he thought were due to a form of silicosis—a view which is shared by J. Freeman in this country (personal communication).

In the present series Case I had an acute illness with complete resolution of the lung lesions clinically and radiologically. Case II had an acute illness which was called pneumonia, which resolved clinically, and which, although not studied radiologically, must have left few if any traces in the lungs for him to be passed as normal at a tuberculosis clinic soon afterwards. He returned to fresh exposure to the dust, becoming ill again with lung lesions, which advanced between the time of his first being seen and his admission to hospital (Figs. 5 and 6) and which to date show no sign of resolution (Fig. 7), although he has improved symptomatically. Case III, seen once only as an out-patient, would appear to be in the stage of resolution; and Case IV, also seen as an out-patient, may be going to resolve or might progress to the fibrotic type of lesion seen in Case II.

It would appear that exposure to bagasse dust is capable of initiating a pathological process in the lungs, the complete resolution of which is possible with a return to normal (Jamison and Hopkins, 1941) as in Cases I and III, or which may progress to a lesion the nature of which is probably fibrotic—Cases II and IV. In this connexion it is noteworthy that Cases I and III had least and Cases II and IV most exposure to the dust in point of time.

Although bagasse contains silica in an amount capable of producing silicosis, the acute pneumonic phase of the illness which these workers experience is unlike any known form of silicosis previously described. Further, the men who at the final stage of the process are also exposed to a silica-containing dust are never ill. A pathogenic organism has not been isolated from the sputum in the acute stage of the disease, and an examination of 15 consecutive 24-hour specimens of sputum from Case II failed to isolate any yeast or fungus. It seemed possible that an allergic factor might be responsible for the disease, the workers becoming sensitized to a protein present in the dust of bagasse. Extracts for skin tests were therefore made as follows:

Twenty grammes of coarsely crushed bagasse was placed in 200 ml. of menstruum with 0.25% tricresol added, and allowed to stand five days with occasional shaking. Four extracts were made in: (1) N/10 NaOH; (2) N/10 HCl; (3) normal saline; (4) 30% alcohol in distilled water. After five days all were passed through a Seitz filter. Extracts 1 and 2 were neutralized with equal quantities of N/10 H_2SO_4 and N/10 NaOH respectively. In both a flocculent precipitate formed. This was used as a suspension. The others (3 and 4) were used as clear yellow fluids as they came through the filter. For each antigen a control was made of menstruum with 0.25% tricresol. The antigens so prepared were tested on Case II by the scratch technique, when all gave negative results. They were then retested by intradermal injection of 0.2 ml. Extracts 1, 2, and 4 all gave a wheal maximal in half an hour and thereafter subsiding, and a flare maximal in 36 hours measuring 35, 30, and 40 mm. respectively. The normal saline extract No. 3 gave no wheal, but a flare developed which reached a maximum of 40 mm. in 36 hours. It was also painless, whereas Nos. 1 and 4 were painful. Four laboratory workers, all of whom had handled bagasse and crushed it with the liberation of a quantity of fine light dust, were then tested with the saline extract by intradermal injection, and all gave negative results. Nine volunteers from the nursing staff who had never been in contact with bagasse were also tested, with negative results. Six employees at the factory were also tested. Four of these gave negative results; they had worked at various places in the factory but not at the bale-breaking machine, and two were as strongly positive as Case II, and were Cases III and IV. Of 20 individuals tested, therefore, the only three who gave positive reactions were Cases II, III, and IV. A similar saline extract was then made of light dust which had settled on ledges in that part of the factory where the board is sawn. This, as stated above, contains no protein, which is removed in process of manufacture. Tests with this extract made on Cases II, III, and IV all gave negative results.

It seems certain, therefore, that whole bagasse contains an antigen soluble in normal saline to which workers who inhale the dust can become sensitized. The acute phase of bagassosis is possibly an allergic response in the lungs to this antigen with, but more probably without, an infective element. The nature of the chronic pathological process is obscure. It might be due to: (1) a form of silicosis which supervenes upon the allergic phase during or after the latter's resolution; (2) a response on the part of the lungs to crystalline cellulose; (3) a chronic process of fibrotic nature occurring in tissues oedematous from their allergic response to the antigen. The conception of chronic allergy is foreign to pathological thought at the present time, but fibrosis is known to occur in lymphatic tissue oedematous for some time from any cause, and this explanation of the lung changes in these cases might be subsequently found to have a parallel in some of the more common diseases of chronic nature whose aetiology is at present obscure, such as rheumatoid arthritis.

Opportunities for the study of the morbid anatomy of the condition have not yet occurred, and attempts to reproduce the disease in experimental animals have so far failed.

Summary

An industrial lung disease is described and a theory of its causation which may link it with more common chronic diseases is advanced. It is suggested that the disease should be called bagassosis and not bagasscosis, as it has formerly been named.

Our thanks are due to Dr. J. N. Deacon, superintendent of the hospital, for permission to publish this paper, to the members of the pathological and nursing staffs who acted as normal controls, and to the management of the factory for details of their manufacturing process and facilities freely granted for visiting the factory and performing tests upon some of their employees.

INTRAMURAL INTESTINAL HAEMORRHAGE

BY

D. CROMIE, M.B., B.Ch.Belf., F.R.C.S.Ed.
Honorary Surgeon, Newton Abbot Hospital

The following is an account of an unusual case occurring in a woman who was operated on because of signs of an acute abdomen. The peritoneal cavity was found to be full of blood, the source of the haemorrhage being traced to a haematoma of the wall of the caecum which had ruptured.

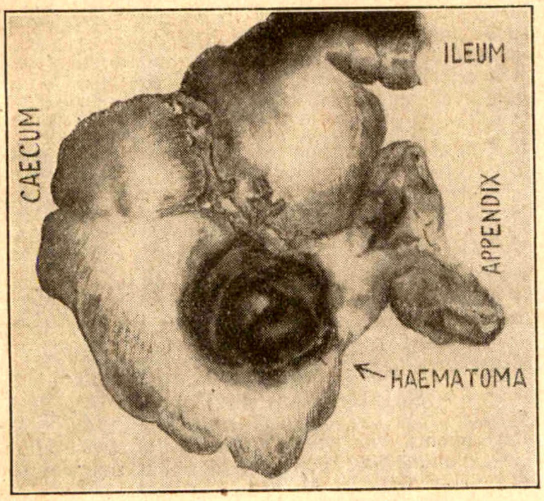
Case Report

The patient, a married woman aged 51, was admitted to Newton Abbot Hospital on Feb. 1, 1941. There had been no former illness of note. On Jan. 30 she had had sudden acute pain over the lower abdomen, had vomited, and had had a little diarrhoea. The temperature and pulse were slightly raised, and there was some abdominal tenderness but no rigidity. On Jan. 31 the condition was unaltered except that no further vomiting had occurred and the diarrhoea had stopped. On Feb. 1 the pain increased, settling in the right iliac fossa, and the right lower abdominal quadrant showed both tenderness and rigidity. The temperature was 99° F. and the pulse rate 90. In the afternoon the temperature rose to 100° F. and the pulse rate to 120. Acute appendicitis was diagnosed (pelvic variety), and it was decided to do a laparotomy, a right paramedian incision being made on account of the patient's sex and the unusual features of the case.

Findings at Operation.—The peritoneal cavity was full of blood, as in a case of ruptured tubal pregnancy. On exploration, however, this cause was excluded, but in the right iliac fossa a lump was found which seemed to be attached to the caecum. As the latter was mobile it was possible to deliver it, along with the tumour, through the abdominal wound. It was then seen that the appendix was thickened and inflamed and that there was a considerable deposit of fat in and around the meso-appendix. A groove separated its base from the tumour, which was a plum-coloured swelling, measuring 2 by 1½ in., situated on the lateral wall of the caecum (see illustration). Its appearance was that of a subserous haematoma, and the site of escape of the blood into the peritoneal cavity was indicated by a ragged tear in the serous coat, 1½ by 1 in. in size. On section the interior of the mass was found to consist of blood clot, and careful examination revealed no perforation into the lumen of the bowel. Around the tumour and beyond its confines the caecal wall was normal.

Operative Treatment.—There was enough space between the ileo-caecal valve and the base of the appendix to allow of resection of that part of the caecal wall which contained the haematoma and the base of the appendix. This was done, and the caecal wall was repaired with layers of sutures, the abdomen being closed without drainage. Except for a slight rise of temperature for 3 days, convalescence was uneventful and the patient made a good recovery, leaving hospital on Feb. 19.

Morbid Anatomy and Histology.—As already mentioned, the naked-eye appearances of the tumour were those of a subserous haematoma. On opening the caecum several small worms were noted lying free in the lumen ; these were afterwards identified as whip-worms (*Trichocephalus dispar*). Pieces of tissue were taken for microscopical examination from the centre of the tumour mass, and, after embedding and section, stained with haematoxylin and eosin. The sections of the appendix and intestine showed acute and chronic inflammation, oedema, and haemorrhage. The bleeding seemed to have infiltrated both muscular layers of the intestines and was also seen in the subperitoneal part of the appendix. The exact site of origin of the haemorrhage cannot be determined, and there was no evidence of tumour formation or of any specific granuloma in the sections examined (J. T. Quinlan).



Commentary

The condition described appears to be unusual, as a search of the literature failed to reveal an account of any similar case. The predominant feature was the large circumscribed haemorrhage in the wall of the caecum. Except for the inflamed appendix there were no other signs of infection, and no evidence of spread of infection along the base of the appendix to the caecum. Following upon the operation, investigations were made of the blood count, the bleeding, and the clotting time, but neither these nor other clinical manifestations gave any evidence of an underlying haemorrhagic diathesis. Moreover, the whip-worms, which were lying free in the lumen of the caecum, were clearly playing no part in the aetiology. These are common enough inhabitants of that organ. Three possibilities offer themselves as likely explanations, and these may be considered in turn.

Trauma.—There was no history of a blow on the abdomen or similar violent injury as one would have expected had the haematoma been caused by direct violence. Further, owing to the mobility of the caecum a lesser degree of injury, unnoticed by the patient, could scarcely have caused the haemorrhage.

Torsion of Caecum with Venous Congestion.—Embolism or thrombosis of the ileo-caecal artery could not be demonstrated at operation, and the naked-eye appearances did not resemble those of the case reported by Harris. If infarction was the cause it must have been in the terminal branch of the posterior division of the ileo-caecal artery. It is possible, however, that the acute inflammation of the appendix may have been associated pre-operatively with an incomplete torsion of the caecum, leading to venous congestion, capillary rupture, and haematoma formation, the condition of torsion then reducing itself before the abdomen was opened.

Infection.—The absence of any signs of an infective lesion involving either the caecum or the ileum has already been mentioned. I am aware, however, that haemorrhage into the bowel wall may occur in terminal ileitis, or "Crohn's disease," and it is possible that the findings in the above case might have some bearing on the causal factors involved in that condition. Jackman has cited instances of intramural haemorrhage in the disease. In these the terminal ileum was involved, and the haemorrhages were invariably small, scattered diffusely in the submucous and interstitial layers of the bowel wall, and distributed over a considerable length of gut, their cause and spread apparently taking the lines of least resistance. Regional and terminal ileitis may also involve the caecum, and some authorities advocate removal of the latter along with the terminal ileum. The preponderance of opinion favours conservative measures. The caecum may become so thickened and fibrosed, however, that mechanical obstruction results, making excision necessary. Had the serous coat of the bowel not ruptured and no operation been performed in the above case the haemorrhage might gradually have been absorbed and been replaced by fibrous tissue, the resulting appearance being similar to that of long-standing ileitis. Although in regional ileitis the appearance suggests a chronic infection and the distribution and size of the haemorrhages differ from those seen in the present case, no causal organisms have been found, and it is possible that the infective element may be secondary, the primary lesion arising in some such way as in this case, through mechanical causes such as incomplete torsion of the bowel and haematoma formation.

Summary

An unusual case of haematoma of the caecum, arising without trauma and probably due to incomplete torsion of the bowel, with venous congestion, is described. The possibility of such an accident giving rise to the changes seen in terminal ileitis is discussed.

CHRONIC LEG ULCER IN MYELOGENOUS RETICULOSIS

REPORT OF A CASE

BY

CYRIL JOHN POLSON, M.D., F.R.C.P.
Lecturer in Pathology, University of Leeds ;
Pathologist to St. James's Hospital, Leeds

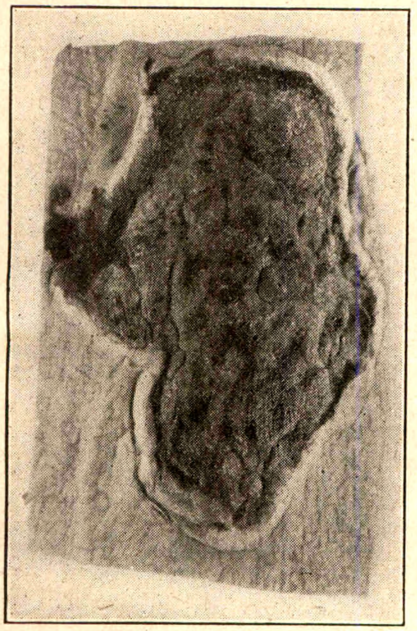
The coincidence of chronic ulceration of the leg and splenomegaly was discussed by Witts (*Journal*, 1942, **2**, 309) when he described two instances of chronic leg ulcer associated with purpura haemorrhagica. From his report it appears that chronic leg ulcer has not been described in association with myelogenous reticulosis. Furthermore, Witts said that "mere size of the spleen is not significant, inasmuch as ulceration is absent in the gross splenomegaly of leukaemia, and present with much less enlargement." An instance of chronic leg ulcer and considerable splenomegaly in a patient suffering from myelogenous reticulosis is therefore here put on record.

Case History

The patient was a woman aged 72 who had been "off colour" for three months, and had had a purpuric eruption beneath the skin of the legs and upper part of the chest. She also complained of painful swellings of the joints of the hands, loss of weight, poor appetite, and severe constipation. When examined in Oct., 1940, petechial haemorrhages were numerous beneath the skin of the arms, hips, left shoulder, and back ; some of the haemorrhages were ecchymoses. Splenomegaly was detected, the lower pole of the spleen being about two fingerbreadths below the left costal margin ; there was slight enlargement of the liver.

A series of seven blood examinations made during Oct. and Nov., 1940, showed that the haemoglobin percentage lay between 60 and 70 ; the red cells averaged three millions per c.mm.; the colour index was 0.87; and the mean diameter of the red cells was 7 μ. The leucocytes at no time exceeded 8,400 per c.mm., and on one occasion were as few as 3,000, 48% of the cells being neutrophil polymorphs and 52% lymphocytes; no abnormal white cells were seen. The Rehfuss test meal demonstrated free acid in the gastric juice, with a maximum level of 40 units.

The patient left the hospital on Nov. 18, 1940, and was not seen again until Dec. 16, 1941, when she was readmitted on account of ulceration, thought malignant, on the inner side of the leg. It was of uncertain duration, but was probably several weeks old. She was now pale and anaemic. The lower pole of the spleen was felt about 5 in. below the left costal margin, and its anterior border was almost in the abdominal midline. There was a purpuric eruption on the limbs and the anterior wall of the chest. An oval ulcer, 2¾ by 2¼ in., was present on the inner aspect of the middle third of the left leg. It had a circumvallate appearance, particularly in the lower half of the ulcer (see Fig.). The margin was regular around the greater part of the ulcer's periphery; it was approximately 1/10 in. broad, raised by 1/10 in., and covered by thinned epidermis; there was no appreciable induration of the margin. The ulcerated area was occupied by dark-red vascular tissue, which bled readily when handled. This tissue was somewhat nodular but not indurated; it was covered in most areas by a thin layer of opaque greyish slough. The initial impression of malignancy was countered, on consideration, by the peculiar margin, its regularity, and the general lack of induration. Moreover, radiological examination excluded bone involvement. Biopsy was undertaken, and is responsible for the dark irregular areas at the left centre and left upper portion of the ulcer margin, shown in the photograph. Squamous carcinoma was at once excluded. The outstanding change was a massive infiltration of the ulcer and the adjacent corium by mature and immature white cells of the granular series. The appearances were those of a myelogenous deposit. Blood examination confirmed the presence of myelogenous reticulosis and severe secondary anaemia. The patient now had 43,000 white cells per c.mm., of which 64% were polymorphs, 16% myelocytes, 11% myeloblasts, 5% smear cells, and 4% lymphocytes. Normoblasts were present in the ratio of 24 per 300 nucleated blood cells. No platelet count was made.



The patient was gravely ill when admitted, and died a fortnight later. Treatment was without influence on her general condition; the ulcer remained almost stationary during this final period of observation.

Post-mortem Examination.—In addition to the ulcer of the leg described above, the other pathological changes at necropsy on Dec. 31, 1942, were as follows: Spleen 1,350 g., 9 in. from pole to pole, maximum thickness 3 in.; the pulp was somewhat soft and greyish red in colour, and the Malpighian bodies were obscure. The kidneys were both pale, except that the middle third of the right was destroyed by a congested infarct. Small friable calculi, the largest 1/4 in. in diameter, were present in both kidneys, the largest lying over the pelvic orifice of the right ureter. There was a solitary cholesterol stone, and the gall-bladder showed slight diffuse cholesterosis. No abnormality of note was found elsewhere; the brain and bone marrow were not examined. Histological examination of the tissues demonstrated the usual appearances of myelogenous reticulosis in the spleen, the liver—where the changes were slight—in the skin, and the kidney, where they were accompanied by acute infarction.

Comment

At the time of her readmission to hospital the ulcer was established and she was unable to give a satisfactory account of its earlier phases; its genesis is therefore a matter of speculation. It may have originated in a subcutaneous haemorrhage. There was no evidence of old haemorrhage in the biopsy specimen, and, although slight recent haemorrhage, possibly caused by biopsy, was present in the corium, the abundance of white cells, and their arrangement, are not ascribable to haemorrhage alone. The interpretation preferred is that the ulcer was a result of devitalization of the skin by a subcutaneous myelogenous deposit.

I thank Dr. John Dick, medical superintendent of St. James's Hospital, Leeds, for permission to quote from the clinical records.

Medical Memoranda

A Filtration Method of Sterilizing Sulphanilamide Powder

After experiments with several methods of sterilization the following technique has been evolved. It is simple in operation and quickly carried out.

METHOD

Sterilize by dry heat at 140° C. for one hour an 8-oz. insufflator, the tubes of which have their outer ends plugged with cotton-wool. The jar must contain about a dozen heavy glass beads or marbles. A Seitz positive-pressure filter of 100 c.cm. capacity and fitted with an E.K. disk is sterilized in the autoclave at 15 lb. for 30 minutes.

The filter is washed out with about 20 c.cm. of acetone by pumping it through the disk. This is to remove any water of condensation. Dissolve 20 g. of sulphanilamide in 100 c.cm. of acetone and pour the solution into the filter. Pump this through direct into the sterile insufflator, the cap of which is then immediately replaced and securely clamped down. To the longer tube of the insufflator is connected a short length of rubber tubing, which is closed off with a Hoffman's screw clamp, without removing the wool plug. The outlet tube is then connected to a water-vacuum pump and the acetone evaporated under negative pressure. A slow current of carbon dioxide is passed over the solution during evaporation (which may be accelerated by standing in a water bath at 80° C.). When the contents have assumed the consistency of a thick paste the jar is agitated frequently in order that the beads may prevent the formation of large clumps of crystals. On drying, disconnect the pump. By further agitating the jar by a circular motion for 10 minutes or so the crystals will be broken down to a fine powder. To remove the last traces of acetone reconnect to the pump and alternately evacuate and release the vacuum by opening the clamp at intervals of 10 minutes for about an hour, shaking the jar occasionally. The powder will now be in a finely divided state, dry, and free-running, ready for use.

Samples of the powder obtained were subjected to sterility tests as follows: 0.5 g. of powder was introduced into each of three tubes of nutrient broth and three tubes of Robertson's cooked meat medium. The tubes remained sterile after 7 days' incubation. Further samples were sent for chemical analysis, which proved that the final powder showed no evidence of toxic oxidation products. We claim that this method is simpler than any other as yet described. It can be economically and practically carried out either on a commercial scale or in small cottage hospitals.

We wish to express our indebtedness to Mr. R. G. Minor, Ph.C., F.I.C., City Analyst's Laboratory, Cardiff, for his willing assistance.

W. J. SALTER,
Technician, Pathology Dept., Llandough Hospital, Penarth.
R. H. MORGAN, M.P.S.

Reviews

TEXTBOOKS OF HAEMATOLOGY

Clinical Hematology. By Maxwell M Wintrobe, M.D. (Pp. 792; illustrated. 45s.) London: Henry Kimpton 1942.

Disorders of the Blood: Diagnosis, Pathology, Treatment and Technique. By Lionel E. H. Whitby, M D, F.R.C.P., and C. J. C. Britton, M.D. Fourth edition Churchill's Empire Series. (Pp. 595; illustrated. 28s.) London: J. and A. Churchill. 1942.

Blood Disorders in Children. By I. Newton Kugelmass, M D. (Pp. 897; illustrated. 60s.) London, New York, Toronto: Oxford University Press. 1942.

he advances made in haematology in the interval between the wo wars have stimulated the production of a number of new extbooks. Wintrobe's *Clinical Hematology* is the latest and most complete of these and the one most likely to succeed to he position left vacant by the death of Naegeli. It has the ame wealth of physiological and technical detail, the same readth of treatment, and an even better bibliography. In fact ome 2,400 references are made in the text, so that it is easy o find chapter and verse for almost any statement. At the ame time, perhaps as a corollary of this deference to the literature, we miss the personal touches which made Naegeli's *Blutkrankheiten* so attractive. An account of the origin and evelopment of the cells of the blood is followed by descripions of the erythrocytes and leucocytes, and the platelets and oagulation mechanism. The author then discusses general physical and chemical considerations of the blood as a whole nd the principles and technique of blood examination. This s a subject to which he has made notable contributions, and ndeed the Wintrobe system of blood examination is standard practice in many laboratories in this country. After a general consideration of anaemia and its treatment Wintrobe proceeds o a clinical account of the various blood disorders. It is not possible to criticize a book of this kind fairly without seeing how it stands up to the test of being used in practice over a period of several months. Nevertheless we should conclude provisionally that it is the most exact and comprehensive handbook of diseases of the blood available in English. It is well llustrated, with seven coloured plates and a large number of clinical photographs and diagrams. All this is not to say that t could not be improved. British readers will feel that the space allotted to blood transfusion and the treatment of haemorrhage is far too small. The signal advances made in this field have been largely the work of haematologists, and it is essential hat they should be adequately reported in textbooks of haematology. The clinical grouping of the various blood diseases is capricious. The index is not full enough; it is, indeed, grossly misleading as to the contents of the book. The casual reader or the student in the library can hardly be expected o realize that many subjects are dealt with both in the physio-ogical and in the clinical sections and that there is not a great deal of duplication.

Whitby and Britton's *Disorders of the Blood* has won its way to a fourth edition. The publication of this after three years of war—and in spite of the blockade, the paper restrictions, and the manifold preoccupations of the authors—is in tself a triumph. The book has the same format as Harrison's *Chemical Methods in Clinical Medicine* and deserves an equally honoured place on the laboratory or consulting-room shelf. With 8 excellent coloured plates and nearly 600 pages of text for 28s. it is undoubtedly the best bargain in the department of haematological textbooks. It is not quite so detailed as Wintrobe, but contains as much as the average physician or clinical pathologist needs to know about the blood. The text follows orthodox lines in dealing with the physiology and the disorders of the blood, with an appendix on technique. The arrangement of the clinical sections is to our mind apter and more logical than Wintrobe's. New material in this edition concerns especially the blood pigments, haemorrhagic states, haemolytic anaemias of the newborn, and transfusion. The section on purpuric and haemorrhagic diseases is still the least satisfactory and will probably offer great difficulties to the beginner. It is unfortunate that textbooks do not give figures for the actual frequency of different haemorrhagic states or stress the predominance of the symptomatic ones. It is probably easier for the student also if all the hereditary tendencies to bleed are grouped together. Ligation of the splenic artery hardly deserves mention as a treatment for essential thrombocytopenia. The description of the estimation of prothrombin suggests unfamiliarity with the technique and contains at least one serious error. It is much easier to dry rabbit brain than human brain, and it is in fact very difficult to get a stable dry extract of human brain without using acetone; human brain is best used as a fresh emulsion. Hobson and Witts recommended adding lecithin to snake-venom, not to brain extract, which already contains an excess of the lecithin factor.

Blood Disorders in Children has nearly 1,000 pages and costs £3. Both figures seem excessive and are explained by the fact that it is stuffed with irrelevancies. A reader does not go to a book on disorders of the blood in childhood for details of how to do a white blood count or for diagrams of retention enemata or of fluid feeding by stomach tube. Dr. Kugelmass may like to take photographs of female technicians looking down quite ordinary colorimeters, but we see no reason why he should insert them in a book intended for public purchase. What the blood is like in psittacosis and Oroya fever also has nothing to do with the case. It is not merely that the irrelevancies swell the size and cost of the book; they distort the perspective. Under leukaemia accounts are given of eosinophilic leukaemia, basophilic leukaemia, megakaryocytic leukaemia, erythroleukaemia, and myelomatosis, all of which are excessively rare or do not occur at all in childhood, whereas the account of leukaemia as it actually occurs in childhood is in our opinion poor. The untutored reader might well get the opinion that polycythaemia vera was a common familial disease in children. He will see some quite unnecessary pictures of gloved hands inserting large needles into distended antecubital veins, but will learn nothing of the special tricks and techniques which have been devised for inserting blood via fine needles or catheters into small collapsed veins in infancy. All this is not to say that Dr. Kugelmass's book does not contain many pretty things. The quotations from the poets are apt and the historical notes are pleasant. But selection and compression are essential in scientific publications, and not a style which recalls James Joyce and the family scrapbook. This is a pity, because Dr. Kugelmass is a haematologist of experience. A good monograph on the special haematology of childhood is badly wanted, but Dr. Kugelmass must reduce his book to a quarter the size and price, and tell us more about blood disorders in childhood, before he can hope to fill the gap.

The supply of textbooks of general haematology now exceeds the demand and we must leave them for natural selection and the survival of the fittest. Again and again in reviewing these textbooks we have been struck by the necessity under which authors seem to feel to give long descriptions of the cytology and physiology of the blood. No other branch of medicine seems to demand so much repetition of normal anatomy and physiology. We have spoken before of the need for a cheap international atlas of haematology, and there seems to be equal need for a standard monograph on the physiology of the blood, to prevent all this duplication. Technique is already extremely well described by Regena Beck, whose *Laboratory Manual of Hematologic Technic* is perhaps not as well known as it deserves to be. It is worth pointing out again that the outstanding writings of the new haematology have all been monographs—Janet Vaughan's *Anaemias,* Claude Forkner's *Leukaemia,* and Engelbreth-Holm's *Leukaemia in Animals.* These have not been overloaded with physiology or technique or pictorial art, and we could do with still more precise monographs of the same type.

OBSTETRICS AND GYNAECOLOGY

Recent Advances in Obstetrics and Gynaecology. By Aleck W Bourne, M B., B.Ch, F R.C S, F R.C.O.G, and Leslie H. Williams, M D., M S, F.R C S., F R C.O G. Fifth edition. (Pp 363; illustrated 18s.) London: J. and A. Churchill. 1942

One might be forgiven for wondering if there have been enough recent additions to our knowledge of obstetrics and gynaecology to warrant the publication of a fifth edition at this stage of the war. It is true that the book contains very little that is new since its predecessor was published in 1939, but it is equally true that this 1942 edition is a good one. Much that could no longer be described as recent advances has been omitted, new material has been added to the remaining sections, and one new chapter has been added. It deals with post-natal care and explains the function of a post-natal clinic, the method of examination, and the suggested requirements in the clinic itself. This chapter gives timely emphasis to a most important aspect of preventive medicine. Dr. Rohan Williams has replaced Dr. Courtney Gage as author of the sections dealing with radiology. As might be expected, considerable space is devoted to the subject of *x*-ray pelvimetry, and a well-balanced summary of the present position emphasizes the fact that it is still the clinical examination which is of paramount importance. It is a little surprising that in reviewing the methods of pelvimetry no mention is made of the work of Nicholson of Moreton-in-Marsh, who has devised a technique which gives results of great accuracy. In the gynaecological section an excellent review is given of the present position in the treatment of carcinoma of the cervix. This edition has been very carefully prepared and will be widely appreciated.

X-RAY TREATMENT OF INFECTIONS

Roentgen Treatment of Infections By James F. Kelly, M D, F A C P, with the collaboration of D Arnold Dowell, M D (Pp 432; illustrated $6 00 or 33s) Chicago: The Year Book Publishers, Inc; London: H K Lewis and Co. 1942.

The infections dealt with in this book are gas gangrene (130 pp.), acute peritonitis (60 pp.), post-operative parotitis (14 pp.), and pneumonia (30 pp.), while but 30 pages are devoted to other inflammations. It is thus not a textbook, but rather a piece of special pleading directed at the doctor who may have these particular conditions under his care. In this light the reader will more easily forgive the inaccuracies of the section on *x*-ray physics and the repetition of similar clinical observations and case-management instructions in chapter after chapter. In spite of these defects, and in spite of a style which is neither fluid nor elegant, from these amply recorded clinical data the authors make original contributions to the subject which are of great importance. The reviewer is convinced of the value of *x*-ray therapy in reducing toxaemia, and in saving not only life but also limbs; of the need for starting *x*-ray therapy by means of a portable bedside unit as early as possible in an acute infection, and for giving small doses every 8 or 12 hours during the critical first two or three days of the illness.

The authors are alive to the implications of their work in military surgery, and plead for the use of airborne *x*-ray apparatus in advanced casualty stations. While the book should certainly be read by radiologists, it is particularly to be hoped at this time that the directorates of our medical war services will be impressed with the strength of the case for further investigation at least.

Notes on Books

The therapeutics of eye diseases is one of the finest and most delicate forms of medical treatment. The reactions of the eyes both to diseases and to drugs correspond in their variability with the exceeding delicacy of the tissues of the eye: of their muscles, nerves, and internal optical tissues. The *Handbook of Ocular Therapeutics*, by Dr. SANFORD R. GIFFORD of Chicago, has now reached its third edition (Kimpton, 20s.). It is an excellent book, clearly written, of wide range, and quite up to date. The section dealing with sulphonamides is some indication of this. Dr. Gifford writes very truly on the imperative need for close observation and repetition of all forms of eye treatment both old and new. He says: "A chance series of cases with a fortunate outcome may convert an ophthalmologist . . . into an enthusiastic advocate of a measure which . . . may later prove absolutely worthless. . . . A position of therapeutic nihilism, or of unreasoning scepticism with regard to new agents and methods, is equally fallacious."

A compact little annual which has made itself indispensable to the civil defence organization appears in a revised and enlarged form in the *Fire Protection and A.R.P. Year-Book* (Lomax, Erskine and Co., Ltd., Aldwych House, W.C.2; 7s. 6d., post free). A vast amount of information has been assembled, particularly concerning fire-fighting. Since the first issue of this yearbook the National Fire Service has been welded into a well organized and equipped unit of the defence services, and a feature of this edition is the maps of each region of the country showing the fire force area boundaries. Much information is also given about the resistance of structures to bomb attack protection against bombs, accommodation and equipment o shelters, and the manner of dealing with gas attacks. The boo is not a manual of first aid, but the schedules of equipment fo first-aid posts, wardens' posts, and stretcher and rescue partie are included. These are to be found in A.R.P. memoranda an in various circulars of the Ministry of Health, but it is usefu to have them embodied in a book which is also a directory o civil defence. This is a volume which we welcome but t which we do not wish many happy returns.

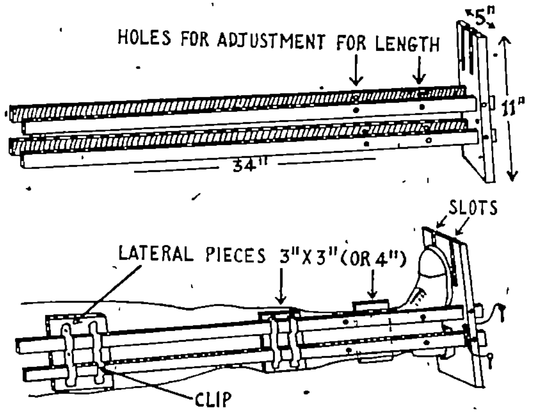
Preparations and Appliances

SPLINT FOR FIRST-AID TREATMENT OF FRACTURES OF THE LEG

Dr. A. P. PHILLIPS, Chaddesley Corbett, nr. Kidderminster writes:

The first-aid treatment of fractures of the lower leg presents problems which have not yet been solved so well as are those of fracture of the femur by the Thomas splint. Many splints suitable for first aid are available—plain wooden splints, Gooch's splinting, Cline's, Liston's (with or without foot-piece), Bryant's, Robert Jones's, and Nevill's. Every one of these, however, has its own limitation—size, width, length, weight, handiness, size of ring, or cost. Also, it is unusual to receive information as to the size and conformation of the patient, and it is surprising how rarely splints will fit patients efficiently and comfortably.

A splint is submitted here which conforms with the demands of surgical principles, is suitable for a wide range of legs, is easily applied, and can be made from plasterers' laths and pieces of wood measuring 3 in. by 4 in. and 11 in. by 5 in. It consists of a foot-piece and lateral bars, two on each side. Two pieces of wood are fitted on each pair of bars. They can be moved along the bars and maintain the bars in a parallel position and provide for pressure to be applied to the thigh and calf. The bars pass through slots cut in the foot-piece and can be adjusted for length by pegs which fit into holes drilled in the side of the foot-piece.



Slings are attached to the bars to support the leg at the lower third and at the knee. The foot is fixed to the foot-piece by a figure-of-eight bandage or a strap. Space between the leg and the bars is filled by padding or bags loosely packed with sawdust. Straps or bandages encircle the limb and splint at the calf and thigh. The slings are made by passing a triangular bandage round the left-hand top bar, under the limb, and over the right-hand bar. One end continues round the splint and limb; the other end is passed between the right-hand bars and brought over the splint and limb to tie to the first end.

Good points in the splint are these: The lateral bars give a good view of the leg. The foot-piece raises the limb from the ground so that the under surface is visible and accessible. The heel is protected from pressure. The slots in the foot-piece make it suitable for a large or small foot. It can be assembled in a minute and packs flat; weight 2 lb.

Very good suspension and encirclement can be achieved by the use of lengths of puttee. They can be fixed by rolling a wooden tongue spatula in the end of the sling, applying it alongside the bar, and securing it by metal rings which slide along the bars and slip over the ends of the spatula which project from the puttee sling.

The splint has been made for me by Mr. Foyle of this village, at his works.

CLASSIFICATION OF DISEASES AND INJURIES

When a history of medical progress during the second quarter of this century is written an outstanding feature will be found to have been an awakening to the need for accurate knowledge about the incidence of disease. So long as disease was thought of mainly in terms of morbid anatomy and bacteriology, statistics of causes of death and of notifiable disease so nearly satisfied the demand for measures of unhealthiness in population groups that, with an occasional grumble that there was a lot they did not tell us, we made do with them. The shifting of interest from the end-products of disease to its beginnings, and from alleviation to prevention, brought in its train a realization that, when all has been said about deaths and notifications, a vast field of ill-health remains of whose trends and comparative incidence we have no measure and can merely form impressions. A few of our large hospitals have given us statistics of the diseases for which patients were admitted, but financial difficulties have blocked the way to any large-scale classification of hospital cases; and we are profoundly ignorant of the incidence of most diseases which are neither notifiable nor productive of considerable fatality, except in limited population groups such as elementary school children. In the early days of National Health Insurance a sample was taken of the records of panel practitioners and tabulated by the Ministry of Health according to a broad classification of ailments; and the Scottish Health Department went further along this line and provided complete tabulations for several years before the war. To our American friends, however, must be given the credit for whole-hearted efforts to penetrate the veil of obscurity, notably by house-to-house recording of illnesses in selected areas and by the preparation of up-to-date standard nomenclatures and classifications of diseases and injuries.

The American work on nomenclature was initiated by the New York Academy of Medicine in 1928, leading to national conferences and the publication in 1933 of the first edition of the *Standard Classified Nomenclature of Disease* with Dr. H. B. Logie as Editor. Apart from a few hospitals such as the Radcliffe, which have made extensive use of "Logie," and one official department which has found in it a mine of information, this notable work has not attracted in this country the attention it deserved. After the appearance of the second edition in 1935 the American Medical Association took over the responsibility for its periodic revision, and following a national conference in 1940 with Prof. Haven Emerson as chairman, we now have an enlarged and revised third edition edited by Dr. E. P. Jordan, which includes also the first serious attempt at a standard nomenclature of operations.[1] The Standard Nomenclature endeavours to include every disease which is clinically recognizable, to avoid repetition and overlapping and to distinguish diseases from their manifestations, thus removing some of the grave faults of most nomenclatures. It is based on a dual system of coding, topographical and aetiological, the first part of the code defining the portion or portions of the body concerned, while the second, separated from the first by a hyphen, defines the cause of the disorder. The first digit denotes the main bodily system, and the next two digits denote the tissues and anatomical sites; diseases of the knee-joint, for example, are prefaced by 248-, 2.. denoting the musculo-skeletal system and 24. joints in general. In the aetiological part of the code the first digit denotes the general category of causation and the remaining digits the subgroups into which each is divided; rachitic affections, for example, are denoted by 764, 7.. denoting diseases due to disorders of metabolism, growth, or nutrition, 76. vitamin deprivation, and 764 vitamin D deprivation. Deformity of the knee-joint due to rickets, therefore, has the code number 248-764.

For card-indexing of hospital cases and for research on specific diseases or manifestations of disease this system is admirable, but for the compilation of morbidity statistics in general it is unsuited and not intended. For the latter purpose we require a classification rather than a nomenclature, so constructed that it can be readily condensed into any groups likely to be needed in tabulations while providing enough detail for all save the most specialized statistical research on morbidity. In America two classifications of this type are under trial—the Classified List of Diagnoses prepared for hospital use by the Welfare Council of New York and the List of Diagnosis Categories for Morbidity Tabulations drawn up by the U.S. Public Health Service and Vital Statistics Division. The latter, built upon the framework of the International List of Causes of Death, is well suited for general public health purposes but is not sufficiently detailed to serve many research needs or for classification of war injuries.

The depth of our ignorance about the kind of injuries sustained by civilians in the present war, from a quantitative standpoint, led the committee responsible for preparing a medical history of the war to seek for a classification to apply to E.M.S. hospital records; and at an earlier date a similar search for a classification emanated from the Medical Advisory Council of the Nuffield Provincial Hospitals Trust at the instigation of Prof. G. E. Gask, who has for many years been interested in improving the utility of hospital records. The outcome was the appointment of a Medical Research Council Committee to draw up a classification to serve all such purposes, and this committee has virtually completed its work and will shortly publish the results. It must suffice to say now that it is based generally on the International List and is comparable with it, thus fulfilling the desires of successive international conferences whose delegates have looked forward to the introduction of morbidity classification. The application of the list to E.M.S. records has already started, and it is hoped that the Nuffield Provincial Hospitals Trust will try out the system in two or three representative regions with the idea of a national application if it proves successful. It would seem that we are, by compulsion of war, coming more rapidly within sight of another milestone in the history of medical statistics and research.

VITAMINS AND CAPACITY FOR WORK

It has long been known that certain vitamin deficiencies lead to diminished capacity for mental and physical work. It is not altogether surprising that a popular belief has lately grown, no doubt also fostered by some of those with an axe to grind or a vitamin to sell, that a superabundance of these vitamins may produce extraordinary stamina and increased well-being and vigour. Scientific evidence has so far been scanty and contradictory, but several papers have appeared lately which throw considerable light on the relation of vitamins to the efficiency of body and mind. Keys and Henschel[1] studied in the course of 10 months physiological and biochemical responses to severe exercise of 26 soldiers receiving the standard U.S. Army Post rations. During part of the study the men were given daily supplements of vitamins; during the remainder, placebos identical in taste and appearance with the vitamin capsules. The exercise consisted in marching in full kit on a motor-driven treadmill for 15 minutes to 3½ hours at a speed of 3.85 miles per hour and an angle of climb of 10% or 12.5%. Elaborate precautions were taken to eliminate effects of training, etc. Several series of experiments were carried out. The daily vitamin additions varied from series to series and consisted of 5 to 17 mg. of vitamin B_1, 100 mg. of nicotinic acid amide, 20 mg. of calcium pantothenate, 10 mg. of riboflavin, 10 mg. of vitamin B_6, and 100 to 200 mg. of ascorbic acid. The army ration itself supplied on the average 1.7 mg. of vitamin B_1, 2.4 mg. of riboflavin, and 70 mg. of ascorbic acid. The pulse rate, heart size, stroke output of the heart, oxygen consumption, respiratory quotient, the urinary excretion of nitrogen and of ketone bodies, and the concentrations in the blood of sugar, haemoglobin, and ketone bodies were measured. No evidence whatever was found of any effects of the vitamin additions on muscular ability, endurance, resistance to fatigue, or recovery from exertion. Keys and Henschel concluded that no useful purpose would be served by enrichment of present U.S. Army garrison rations with the vitamins studied.

---

[1] *Standard Nomenclature of Disease and Standard Nomenclature of Operations.* Edited by Edwin P. Jordan, M.D. Chicago: American Medical Association.

Another group of American workers,[2] while accepting the correctness of Keys and Henschel's results, have expressed doubts whether these negative findings may be generalized, first because they dealt with only one type of work, and, secondly, because functions of the central nervous system had not been studied. Simonson and his co-workers[2] therefore set out to gather further evidence. They examined 23 people, all in good health. Twelve of them were given daily tablets, containing 6 mg. of vitamin B_1, 80 mg. of nicotinic acid amide, 8 mg. of riboflavin, 3 mg. of vitamin B_6, and a certain quantity of filtrate factors; eleven received placebo tablets, but believed that these were vitamin preparations. All carried on with their customary diet under usual working and living conditions. The following reactions were studied: Endurance in dynamic work, endurance in static work, recovery of working capacity, maximum muscular force, fatigue of maximum voluntary effort, heart rate, maximum frequency of finger movements, Kraepelin's test for mental work, subjective sensations, and finally the fusion frequency of flicker—that is, the rate of successive light stimuli necessary to produce an effect equal to continuous illumination. According to Simonson and his colleagues[2] there is evidence that this test reflects the general fatigue of the central nervous system. The results showed that the supplements administered did not improve the performance of any of the different types of muscular work, and the results of the Kraepelin test were doubtful. The fusion frequency of flicker was increased, however, in 8 out of 12 persons taking the vitamin tablets, and there was no change in any of the controls. Subjectively, 8 people out of 12 felt more alert after vitamin supplements. In 3 of the 4 who did not the fusion frequency of flicker was also not improved. In the control group subjective improvement was reported by 1 person. Simonson and co-workers feel that as their subjects were perfectly healthy and normal it would be reasonable to expect a favourable effect of an increased intake of the vitamin B complex on the capacity for mental work of the majority of normal people. In their opinion additional vitamin B would benefit the working capacity in the manifold occupations where fatigue is primarily due to fatigue of the central nervous system. It is regrettable that no information was given about the vitamin content of the diets used in this study. Though they are unlikely to have been of the same standard of excellence as the American Army diets, they may well have been at least equal to the wartime ration of the population of this country. It is not known which factor of the vitamin B complex was primarily involved, but work done at the Mayo Clinic underlines the importance of vitamin B_1. Williams and Mason[3] studied there the behaviour of women partaking of diets low in vitamin B_1 (supplying only some 150 i.u. daily), but little different in this respect or in general composition from the diets of thousands of American families with the exception that all other known vitamins were added in liberal amounts. Apart from anaemia which developed in five of the women, all became depressed, irritable, and quarrelsome. They were inattentive to details of their work, confused in thought, uncertain in memory, and lacked manual dexterity. All these symptoms disappeared when, unknown to the women, vitamin B_1 was added to their diet.

With the introduction of flour of 85% extraction the vitamin B_1 intake in this country is probably on an appreciably higher scale than in the Mayo experiments. Yet for heavy manual labour, long hours of work, and the nervous strain of war, even this may not be optimal. The effects of rationing of meat and milk on riboflavin and nicotinic acid in our diet must be carefully watched. It is imperative to make sure that the vitamin content of our rations is adequate to support the sustained mental and physical effort we are all called upon to make, and it is gratifying to learn that the necessary scientific inquiries are already taking shape.

RECTAL GLUCOSE

The administration of fluid by the rectum is a well-established procedure, and there is no doubt that if care is taken to master a few details in technique it provides a valuable means of giving fluid. The method is chiefly used where oral feeding is inadequate or impossible, as in cases of dehydration—"drying" (*pace* A. P. Herbert) is hardly the apt word here—and severe vomiting and after operation, and the temptation to "doctor" the fluid in the hope that the rectal route may provide a means of feeding the patient or administering drugs is almost irresistible. Unfortunately, however, this is not as easy as might have been hoped, and a paper by Garrer, Groen, and Hallen[4] on the absorption of glucose from the rectum comes as a timely reminder that we may not only deceive ourselves as to the benefit derived by the patient from glucose per rectum, but also, in days when every grain of sugar is of value to the country, we may be going to much trouble and expense to no good purpose. The authors describe a series of experiments performed on four healthy adults in which amounts of glucose varying from 5 to 40 g. in 40 c.cm. of distilled water were introduced into the rectum and retained for periods varying from one to two hours. The rectum was then emptied by spontaneous defaecation and subsequent lavage, and the amount of glucose returned was estimated. An initial series of control experiments was made to satisfy the investigators that by this method nearly 100% of the glucose was recovered after immediate defaecation. Small enemas were used, as it was intended that they should emain in the rectum and not ascend into the sigmoid. Blood-sugar determinations were made at half-hourly ntervals for four hours. The results showed that glucose s absorbed from the rectum only very slowly, at less than one-tenth the rate of absorption from the duodenum, and a very large proportion of the sugar is recovered in the rectal washings. In no case was there any significant rise of the blood sugar. The extremely slow rate of absorption, less than 1 g. per hour, together with the fact that glucose, galactose, and laevulose are absorbed at a uniform rate, suggests that the absorption of glucose takes place by simple diffusion only.

These findings correspond with those of most other investigators in this field. In the small intestine, on the other hand, absorption of glucose is much faster and appears to be an active chemical process, which is specific for the different sugars and requires the function of living cells; an essential step is the phosphorylation of the molecule. There is practically no phosphatase present in the rectal mucosa, but it is abundantly present in the small intestine. The few observers who have noticed a significant rise of blood sugar after giving glucose per rectum have either used large quantities of fluid, in which case the enema certainly reaches the colon and may even regurgitate into the ileum, or have used massive doses of glucose. In practice the former method is unsuitable for ward administration, and, though the latter may be justified in certain selected cases where the intravenous route is contraindicated, it is notoriously difficult to retain the enema, and the method will always entail a large wastage of glucose. Avery Jones and Naunton Morgan[5] found that tap water was the most satisfactory solution to administer by rectum, though to avoid depletion of sodium chloride it was perhaps better to add one volume of normal saline to four volumes of tap water. In any event, we should do well to abandon any idea of rectal feeding, while realizing the enormous value of rectal administration of fluid in the treatment of dehydration.

HAEMORRHAGE FROM GASTRITIS

Gastric haemorrhage may often give rise to great perplexity when, in spite of careful investigation, no obvious cause for the bleeding can be found. Not infrequently cases of severe and repeated haematemeses are seen in which history and radiography can with some certainty exclude at least chronic peptic ulcer. E. B. Benedict,[6] writing on this subject, reports one such case in which nine severe or moderately severe gastric haemorrhages occurred during a course of six years in a patient who had had a gastro-enterostomy performed at the age of 16. In this case no ulcer was found, and subtotal gastrectomy, which was finally carried out, demonstrated chronic gastritis. Such severe bleeding from gastro-jejunitis has been previously noted by others, including Hurst, Faber, and Montier, and most practitioners are able to call to mind "obscure" cases of perhaps severe and sometimes repeated haemorrhage for which no quite satisfactory explanation has at the time been offered. Since the introduction, however, of the flexible gastroscope more precise knowledge as to gastric haemorrhage has been available. Benedict now reports the findings in 213 cases of gastritis, among which there was bleeding in almost exactly 20%. Among his interesting observations are the following. Of 42 patients with gastroscopic evidence of gastritis (all of whom had bled), in only 9 was there radiological indication of any pathological gastro-intestinal change. Among these 42 patients all types of gastric mucosal changes were seen—superficial, atrophic, and hypertrophic—which, as Benedict points out, must often be difficult or impossible to demonstrate radiologically. In a further series of 24 cases in which gastritis and peptic ulcer were thought to be present together, Benedict suggested that bleeding was in fact the result of gastritis rather than of the ulcer, because some of these showed no clear evidence of active ulceration, and all had gastroscopic evidence of gastritis.

Post-mortem evidence of gastric haemorrhage and gastritis is notoriously difficult to assess, but the combination of careful clinical examination with negative *x*-ray findings and a positive gastroscopic report leaves little doubt as to the occurrence of bleeding from simple gastritis. But a "normal" *x*-ray report does not necessarily exclude peptic ulcer, and it is well known how rapidly an ulcer may heal after severe haemorrhage; negative radiographic findings two or three weeks after the bleeding had ceased are therefore inconclusive. Benedict's figures are, however, of importance as indicating the relative frequency with which non-ulcerative gastritis may bleed, and as explaining the cause of some at least of the often unexplained haematemeses which the sceptical may still wish to think of as "gastrostaxis." Superficial erosions, mucosal inflammation, and ulceration may all heal rapidly, and an acute sudden gastric haemorrhage may leave little trace even gastroscopically when examined within only a very short time of the bleeding. Even such common drugs as aspirin may provoke mucosal bleeding, and the increasing evidence of gastroscopy is gradually lowering the incidence of "spontaneous" gastrostaxis to smaller and smaller proportions. It is not yet sufficiently realized that in gastritis the stomach may bleed and bleed severely, that the symptoms may be slight, the physical signs few, and radiological demonstration impossible.

CAUSTIC BURNS OF THE EYE

Caustic burns of the eye present a difficult problem, for the late results are nearly always much more severe than would be expected from the immediate effects of the injury. It is possible that some of these late results are inevitable, owing to delayed appearance of irreversible damage produced at the time of the injury. A more hopeful approach was suggested by the work of Denig, who held that the thickening of the cornea that develops in such cases was brought about by the irritating effect of damaged and necrotic conjunctiva. With this in view immediate mucous membrane grafting of burnt conjunctival surfaces was practised by him, a procedure that has met with only partial success in the hands of other surgeons. The technical difficulties of mucous membrane transplants on a damaged septic surface are not altogether insignificant, and death of the transplant is not uncommon. Although the view that corneal damage is due exclusively to the irritative products of the burnt conjunctiva may not be substantiated, there is much room for technical improvement. A useful study on these lines has come from A. L. Brown.[1] In the experimental rabbit he showed that burns of the conjunctiva, particularly of the palpebral conjunctiva, have a disastrous effect on the cornea. Whenever two burnt surfaces are in apposition—and this holds good of the skin of the rabbit as well as the cornea and conjunctiva—the sequelae are always more severe. Some control of the necrosing process in the cornea could be obtained by the introduction of a layer of tissue separating the burnt conjunctiva from the cornea. Brown used rabbit's peritoneum for the purpose. This procedure, applied clinically, gave good results. It is a fairly simple matter to introduce a strip of peritoneum into the conjunctival sac and to keep it *in situ*; and judging by the clinical results in four cases the procedure has much to recommend it for the protection of the cornea, though of course it does not influence scarring and contraction of the lids to any extent. Brown's results are supported by two other observers, E. L. Bulson[2] and R. J. Masters, who obtained substantially the same experimental results, though they leave open the question whether rabbit's peritoneum is the best protective membrane. It seems essential that if peritoneum is used it should be as thin as possible and free from adherent tissue. One possibility that suggests itself is the use of amniotic membrane.

MICROGLIA AND NERVES IN POSTERIOR PITUITARY

Although it has been asserted that notwithstanding the existence of microglia in all other parts of the central nervous system it is absent in the posterior lobe of the pituitary body, a clear demonstration of its presence in the pars nervosa has now been achieved by Dr. E. Vasquez-Lopez,[4] working in the laboratories of the Imperial Cancer Research Fund at Mill Hill. Hitherto research workers have failed to demonstrate beyond doubt microglial elements in the neurohypophysis, partly owing to technical difficulties and partly because their attention was directed chiefly to the glandular part of the organ. Vasquez-Lopez has worked principally on the neurohypophysis of the horse, which he has found to be well suited for the purpose owing to the looseness of its texture. He has, however, obtained confirmatory evidence from the pituitaries of the ox and the rabbit, notwithstanding the greater density of the glial tissue in these animals. He has also shown that the microglial tissue of the pars nervosa is continuous through the stalk with the microglial elements of the hypothalamic centres to which the organ is anatomically and functionally related. The form assumed by the microglial elements is characteristic of the initial stages of mobilization of these cells, and transitional stages between the fixed and mobile states are represented in the pars nervosa, tuber cinereum, and supra-optic nuclei. Moreover, between the epithelial cells of the pars intermedia, near its junction with the pars nervosa, there are peculiar cells which the author believes to be migrated microglial cells. This is interesting not only because, in his opinion, these cells may be migratory phagocytic cells, but also, from the genetical standpoint, because cells in this position may be related to the normal outgrowth of tubular diverticula into the surrounding vascular tissue from the apex of the infundibulum in Lepidosiren which constitutes what is known as the "infundibular gland." Further study of the microscopical structure of the neurohypophysis in Lepidosiren and other genera in which this organ is more highly differentiated than in mammals might yield valuable results with respect to its structure, nerve supply, and function in mammals, in which this part of the hypophysis appears to be undergoing regression.

Notwithstanding the demonstration by Cajal more than 50 years ago of the existence of nerve fibres in the posterior lobe of the hypophysis, their presence there has been regarded with much scepticism. The existence of nerve fibres in the posterior lobe has now been conclusively demonstrated by Vasquez-Lopez,[5] [6] and he has also confirmed the view that morphologically the pituicytes are only neuroglial cells; the nerves of the hypophysis do not, as has been thought by some, end in relation to the pituicytes, and the way in which they end does not correspond with the usual mode of termination of secretory nerves. It is thus considered that these nerves may be afferent sensory fibres such as those leading from the carotid body and carotid sinus. The terminal nerve fibres end in bulbous swellings, club-shaped structures, and menisci, and in the horse the nerve filaments with their end-organs form a network round the vessels in the fibrous capsule covering the distal pole of the posterior lobe. These terminal bulbs are spoken of by the author as "terminal meningeal corpuscles," and he believes that the impulses arising in them are conveyed by the nerves of the posterior lobe to the tuberal and supra-optic nuclei of the hypothalamus. Whether all these nerves are afferent in nature, or whether some are sensory and others efferent secretory nerves, remains to be determined, and it is possible that research by modern histological methods in those animals, such as Heptanchus and Petromyzon, in which tubular outgrowths from the infundibulum penetrate the pars intermedia may throw more light on this difficult problem.

A REVIEW OF THE PUBLIC HEALTH

The second wartime summary of the work of the Ministry of Health, for the year to March 31, 1942,* has appeared with commendable speed after the first, which, though it covered two years, was not published until last February. The year surveyed in the latest report was less eventful than the preceding two, and was mainly one of consolidation and adjustment of the Department's activities. On the credit side the Ministry can report no major epidemic, no falling off in nutritional standards, no increase in mental diseases, no great variation from the normal in either the incidence of or death rates for scarlet fever, measles, influenza, and enteric fever, and a slight fall in the notifications of cerebrospinal fever (11,077 against 12,741), which, however, still remain abnormally high. Notifications of and deaths from diphtheria increased, however, the former from 46,281 to 50,797 and the latter from 2,480 to 2,641, but it is recognized that no substantial improvement can be looked for until at least three-quarters of the children of the country have been immunized (up to June, 1942, well over 3,000,000 had received prophylactic treatment). There was a sharp rise in the year under review in the number of new cases of syphilis, the increase being 40% over the figure for 1940 (civilian and Service cases together), making an increase of 70.5% in the total of new infections during the war. As regards tuberculosis, since the Ministry's report was prepared we have published (Oct. 10, p. 436) the main findings of the Medical Research Council's Committee on Tuberculosis in Wartime, to which reference should be made. The Ministry states that special precautions have been taken against the introduction into this country of typhus fever, also of malaria by possible carriers from malarial regions abroad. Maternal and infant mortality figures showed a slight increase for the year, the maternal death rate being 2.76 (2.60 in 1940) and the infant death rate 59 per 1,000 live births (56 in 1940), but the rate for infections during childbirth and the puerperium fell to 0.47 per 1,000, the lowest yet recorded. All these are the routine facts and figures issued annually by the Department, but the report this year contains an interesting section on hospital development, including a brief history of the E.M.S., a statement of Government policy for the future, and some account of the special treatment centres for head surgery and nervous diseases, and rehabilitation and vocational training schemes. Finally progress is reported in the compilation of the official Medical History of the War under the editorship of Sir Arthur MacNalty.

War Medicine Series

The paper printed below is based on a lecture which was one of a series recently given at the British Postgraduate Medical School, Hammersmith

MALARIA IN WARTIME*

BY

Sir P. H. MANSON-BAHR, M.D., F.R.C.P.

The Quartan Parasite

The quartan is a parasite of children rather than of adults. It is a very local infection. We found a certain amount in Salonika and in Palestine in the last war, but among the troops it amounted to only 1% of the total. It is truly the most beautiful of all malaria parasites. The corpuscle in which it lives does not enlarge; its cycle of development is seventy-two hours, in contradistinction to the benign tertian, and therefore it typically produces fever every four days. If we can believe Sydenham, quartan malaria must have been rife in Westminster in his day, and most of the Members of Parliament were often precluded from their duties by recurrences of this fever. He realized too that it was associated with marshy districts such as prevailed in Westminster at that time.

Another point about the quartan is its ability to split the red corpuscle in twain. There are only eight spores formed, instead of the eighteen to twenty-four in the case of the benign tertian and eighteen to thirty-two in the case of the subtertian. The pigment is rather blacker. Little spots develop inside the corpuscular protoplasm, but they are not Schüffner's dots. In this country they are known as "James's dots," which are little blue specks, not red like Schüffner's. In this form of malaria we do not always see the classical quartan temperature chart, and this is due to the fact that there may be two generations of parasites in the blood, producing a rough kind of quotidian fever.

Plasmodium ovale

The latest arrival in the malaria family is *Plasmodium ovale*, so called because the corpuscle in which it lives tends to become oval in shape. It was discovered in 1922, and was at first looked upon as a freak; but now we know it is a common parasite in West and Central Africa, and it had been confused with the benign tertian because of its tendency to produce Schüffner's dots. The corpuscle becomes ragged, frayed, and oval in shape, presently losing its rounded contour. The parasite has only eight spores, and produces a harmless infection. It is said to have been observed in Central Asia and in Central America, but the general idea is that it is peculiar to Central Africa. *Plasmodium ovale* is now much used in malaria therapy, and is the "star turn" at present at the malaria centre at Horton, Epsom, because it produces efficient rigors when artificially inoculated and does not require any prolonged or drastic treatment, but just fades away directly small doses of quinine are administered. I have seen only one patient who was really seriously ill with this variety.

Drugs used in Treatment of Malaria

With regard to drugs in the treatment of malaria, before the last war we were told—from the teaching of Prof. Dixon in Cambridge—that the most specific-of-all drugs was quinine. Yet as this war progressed we began to disbelieve more and more in its specificity, and had to modify our fundamental ideas. We believe now that quinine is an extraordinarily valuable drug but is definitely selective upon certain stages of the malaria parasite. The species of the parasite on which it acts most quickly is the benign tertian, but we cannot entirely banish it from the human body by one or two or even three doses of quinine. The plasmodium has a way of side-tracking and slipping away into the interstices of the bone marrow and the spleen, ready to emerge again at the next opportunity. This selective action of drugs was brought out strikingly when plasmoquine (pamaquin) was discovered in 1925; but it is not, as you may have thought from reading the literature, an attempt by Germans to synthesize quinine, but is a by-product of methylene-blue, which was employed by Manson in China as a febrifuge many years ago. He formulated the idea—a very clever one—that if there was a selective action of a stain for a particular blood parasite it could be surmised that the same substance might also exert a therapeutic effect, and compounded a combination with borax (Manson's stain), which he proved to be selective for malaria parasites.

When the blood is full of subtertian crescents and plasmoquine is given in sufficient doses this stage of the parasite, which is not amenable to quinine, rapidly disintegrates. The parasites burst at various points; the chromatin degenerates, and finally they vanish from the blood stream.

Atebrin (or mepacrine), an acridine compound, is another dye derived from methylene-blue. It does not affect this crescent stage at all and has no effect upon exflagellation, but causes the pigment to collect in the centre of the parasite.

Diagnosis

It is the differential diagnosis of malaria which is so important. Malaria usually causes enlargement of the spleen, but whether you can tell that this is so or not depends on your skill in palpation. In subtertian malaria the spleen becomes rounded off rather like a tennis-ball, but it is only after repeated malarial attacks that the classical hard edge can be detected. It is therefore not safe to say that a man has not got malaria because the spleen cannot be palpated. There are various ways of performing palpation, and new-comers have to learn the correct technique; and the question arises: When is a spleen not a spleen? The answer is: When it is a kidney! An enlarged left kidney is sometimes mistaken for an enlarged spleen. I recall a major in the Indian Army who drew a pension for eighteen years on the ground of enlarged spleen when in fact what he had was a large left polycystic kidney; and I have even seen this misdiagnosis made when assisted by uroselectan and radiography. There is also splenic pain, which may be significant.

In the diagnosis of malaria the great point to remember is that in a malarious country it may simulate almost any other disease. Subtertian malaria is the greatest mimic. Quite commonly it produces cerebral symptoms—cerebral malaria, due to the congregation of parasites in the brain, sometimes leading to coma and death. I remember how some soldiers marching from Jaffa to Jerusalem in 1918 fell out by the side of the road waiting for the ambulance, and before it could reach them they were dead. Very often in the Near East the worst forms of malaria are found in the winter-time. Mosquitoes once infected remain so, and in winter tend to congregate in buildings and nooks where there is warmth and then descend upon anyone they can find. These dire cerebral forms may crop up during the winter months and may be mistaken for other forms of cerebral disease. In the summer the patient may go down with hyperpyrexia, and so the case may be mistaken for heat-stroke.

I would especially warn against confusing alcoholism with malaria. In a malarious country a man may be accused of being drunk when he is suffering from malaria.

Mania is another thing which may be misleading: the patient may be suffering from subtertian malaria delirium; and, on seeing a sudden epileptic fit, do not jump to the conclusion that it is true epilepsy, for it may be malaria simulating that condition. Then there are attacks simulating cerebrospinal meningitis with pain and stiffness at the back of the neck. There is an appendicular form of malaria that is due to sporulating forms of the parasite which select that particular part of the intestinal canal in which to congregate. When the patient's temperature rises with rigor to 104° F. as a sequel to an abdominal operation, you will want to ask whether malaria parasites were not in the blood before the patient was subjected to operation or whether the operation actually incited the rigor. Cholecystitis is also a dangerous primary diagnosis. Why should an epidemic of cholecystitis in healthy young men suddenly arise? The explanation lies in the hepatic congestion in subtertian malaria, with an acutely distended gall-bladder.

---

* Concluded from p. 462.

Then there is malarial dysentery, or colitis. Malaria is frequently accompanied by diarrhoea; in fact, often there may be diarrhoea and nothing else to guide one. It is very common to see patients from West Africa who have suffered from diarrhoea on the voyage and, owing to this, doctors have prohibited them from taking quinine. I have seen such cases develop cerebral malaria and fatal coma the moment the boat has docked.

In Egypt subtertian parasites have been demonstrated in scrapings made from the bowel. "Malarial dysentery" with blood and mucus in the stools simulates acute bacillary dysentery. It is possible to get such an acute diarrhoea with malaria that it resembles cholera. There were several cholera scares in the last war, but they were due to a choleraic form of subtertian malaria. Then we may meet the icteric forms; but malarial icterus is not a really true obstructive jaundice. In subtertian malaria it is almost diagnostic to get urobilinuria with sherry-coloured urine, and this may sometimes be taken as an index of infection, even in the absence of subtertian parasites in the blood.

I remember in 1916 being asked to see a soldier who had come down from Khartum intensely jaundiced. He was evidently dying. I was then in charge of the laboratory, and found that I had examined his urine and serum, and carried out agglutination tests; but the one specimen that had not been examined was the blood film, which was crammed with subtertian parasites. By the time this was done, however, it was too late! One can meet with forms resembling acute pancreatitis in which the pancreas is affected; others resemble intestinal obstruction, with profuse vomiting. One may even see cardiac forms with generalized oedema, which were frequently encountered in the last war, or, again, pulmonary forms associated with bronchitis or pleurisy. Further, there may be some resembling acute nephritis with blood and cells in the urine; or a cutaneous rash with multiple haemorrhages in the skin, somewhat resembling typhus or measles.

Blackwater Fever

Finally, there is the most dramatic sequel—blackwater fever, solely associated with subtertian malaria. It probably represents an anaphylactic phenomenon due to hypersensitivity to toxins of this parasite. Blackwater fever occurs only in those parts, such as the Jordan Valley, Macedonia, and West Africa, where the subtertian parasite is prevalent. The prevention of blackwater fever is closely linked up with the prevention of malaria, so that if a man does not get infected with the subtertian parasite he will not develop blackwater. If a laboratory service is maintained by which in all cases the blood is examined for malaria the moment the patients fall ill, then the onset of blackwater fever will be prevented. In the years immediately succeeding the last war I never treated less than 4 or 5 cases of blackwater fever here in London every winter; they were usually acute dramatic cases, and the death rate figured between 25% and 50%; but since the rule has been established that all must have their blood examined directly they land in this country from West Africa, blackwater has not been observed. A patient is exposed to the danger of blackwater fever once he has had acute malaria—usually up to nine months. It is apparently a case of supersaturation with this parasite, so that blackwater seldom results after a primary infection. It occurs mostly in the old residents of the Tropics who, on returning to this country, have been exposed to cold and wet or some shock which causes a sudden multiplication of parasites. Then the red blood corpuscles break down and become haemolysed, and the victim may die from blocking of the kidneys with products of their disintegration. If, therefore, this process can be prevented from taking place, then blackwater fever will not ensue. Treatment depends upon the alkalinization of the blood and upon prompt blood transfusions.

The Importance of Blood Examination

The diagnosis of malaria depends upon correct blood examination. The diagnostician must be familiar with all stages of the malaria parasites: he should be so sure of his premisses that he can recognize them as readily as Smith, Brown, or Robinson. But can ordinary unsophisticated folks learn to distinguish these appearances in a reasonably short time? The answer is that they can be taught to do so. In Central Africa there are native dressers who are proficient in spotting parasites. In the last war when put to the test we had to improvise an organization for the detection of malaria at the earliest possible moment for treatment in the field. There originated the diagnosis stations which have now been included in the Army service. Orderlies were chosen from the ranks, some of them with little previous education, and by six weeks' intensive training, by making them look at and stain blood films, we got them sufficiently accurate in discerning malarial parasites to be of great service. A number of these men are still employed here in London at the present time. Those thirty men who were trained were responsible for diagnosing 417,000 blood slides in the last year of the war in Palestine.

Prevention and Treatment

How are we going to prevent malaria in the field? Quinine in large doses is a poison; it may produce amblyopia in some people, and they may become blind. Quinine in enormous doses, as a means of preventing a malarial attack, is a broken reed. It has been shown that one can inject quinine together with malaria parasites into the blood of the recipient and yet produce malaria. On the West Coast of Africa most officials cling to the belief that 5 grains of quinine will prevent malaria and blackwater. It probably modifies the acuteness of the malarial attacks and thereby the proclivity to blackwater fever, but when you give soldiers who are operating in open country 5 grains of quinine a day it has little visible effect in reducing the incidence of malaria. For prevention on a large scale the chief line of defence is the mosquito net. The next best method is to kill the mosquitoes.

With regard to drug treatment of the actual attack, however, quinine still remains the standard. It is most effective in benign tertian malaria and it has also a great effect upon subtertian. But it is necessary to remember that quinine given in big doses to a patient with a large number of subtertian malaria parasites is likely to precipitate blackwater fever by the sudden dissolution of the parasites, and the patient may die within twenty-four hours. For benign tertian malaria, quinine should be given in doses of 10 grains three times a day, and the bowels should be freely kept open. One must go on giving the quinine in decreasing doses for about six weeks, though even this continuous therapy will not extirpate the infection from the body entirely; but to inject quinine intramuscularly to everybody indiscriminately is to ask for trouble, as abscesses and indurations are apt to form in a certain number. At the same time I never hesitate to give quinine intramuscularly when it is necessary as a remedial measure in severe infections. The results are magical if it is given in the right way and injected deeply into the gluteal muscles, but it should never be injected below the folds of the buttocks.

You cannot treat malaria scientifically unless you control treatment by frequent blood examinations and can recognize the changes in the parasites when acted on by quinine or other drugs. Intravenous quinine is reserved for the most severe forms of subtertian malaria. From 5 to 7 grains dissolved in 5 c.cm. of distilled water is quite enough. With regard to plasmoquine, remember also that this is poisonous. When it was first introduced we gave it in too big doses, and were thereby producing poisonous effects. It is now recognized that small amounts of plasmoquine in tablet form—known as plasmoquine compound—are beneficial, each tablet containing 1/6 grain, with 2 or 3 grains of quinine. This, given as a regular course, has been found by the Army in India to be the best method of treating benign tertian malaria and of preventing further relapses. In such cases a start is made with the quinine and continued with plasmoquine compound, the dose of which is two tablets twice a day for a week, amounting to four courses of seven days, with a break of four days between each. This means that about 2/3 grain of plasmoquine is given a day, in addition to 20 grains of quinine. With this method the relapse rate in benign tertian malaria has fallen from 40% to something like 8% in the Army in India.

Plasmoquine and atebrin go badly together, but atebrin and quinine work well in combination. The dose of atebrin is 1/10 gramme three times daily for seven days. It is a yellow tablet which is given by the mouth; but there is also a soluble form which can be injected. It is active especially in the treatment of subtertian malaria, and I have seen only one case in which blackwater fever supervened after atebrin, so it is useful in this direction. I do not believe, however, that it is nearly as effective in treating benign tertian malaria as the method I have outlined. Certain disadvantages of atebrin have been pointed out, and it is well to warn people that they may acquire a somewhat yellowish tinge. I have never seen anybody go "off his head" when taking atebrin, but acute mania in native races has been described after taking it in therapeutic doses, though this certainly does not seem to be common in Europeans.

RECEPTION OF CASUALTIES IN AN E.M.S. HOSPITAL

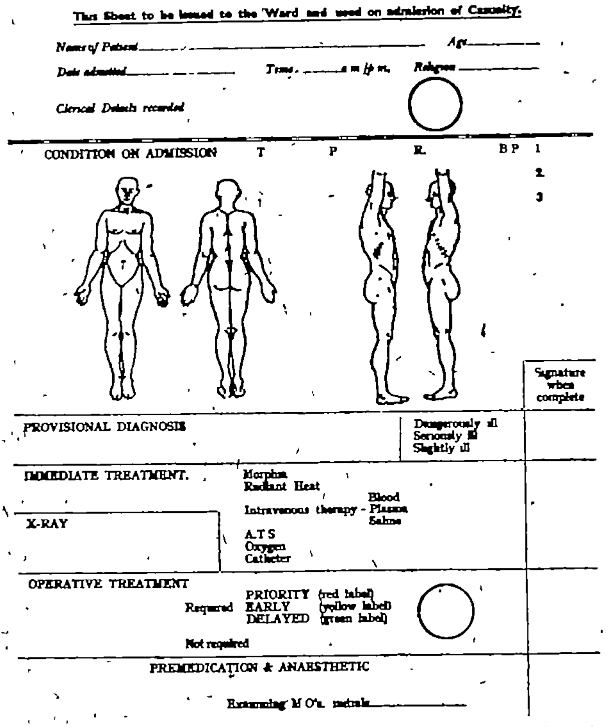
BY

STANLEY J. FIRTH, M.D., M.R.C.S., D.P.H.
Medical Superintendent

AND

HAROLD PARK, M.B., F.R.C.S., F.R.C.S.Ed.
Resident Surgeon
The Municipal Hospital, Brighton

The sudden influx of a number of wartime casualties, whether Service cases or civilian, calls for a procedure different from that used for ordinary peacetime admissions. These casualties are the immediate concern of several separate hospital departments, and it is therefore important that each section should be supplied with the necessary data in the simplest form. With this in view we prepared an urgency admission sheet which has worked very well in actual practice and which, having been thought deserving of praise in high medical quarters, we consider worthy of publication.



This Sheet to be issued to the Ward and used on admission of Casualty.

Name of Patient ________________ *Age* ________
Date admitted ________ *Time* ______ a.m./p.m. *Religion* ________
Clerical Details recorded ○

CONDITION ON ADMISSION T P R. B P 1 2 3

Signature when complete

Required PRIORITY (red label) / EARLY (yellow label) / DELAYED (green label) ○
Not required

PREMEDICATION & ANAESTHETIC

Examining M.O.'s initials ________

This sheet, the front page of which is here reproduced, is hung at the foot of the bed in a temperature-chart holder, and consists of a single piece of paper about the size of the printed page of the *Journal,* printed on both sides. A description of the back of the sheet can be given in a few words. It is divided into two sections, one half being for the operative findings, the other for the post-operative instructions. This side is completed by the anaesthetist during the operation.

The front of the sheet is a record made up of the following sections. It is headed by the name, the Service No. of Service cases, age, date and time of admission, and religion. Immediately below this is a space for the use of the clerical staff, who, having recorded the details which concern them, denote this by affixing their stamp. Next comes a section in which are entered the temperature, pulse, respiration, and blood pressure of the patient, together with a pictorial record of the injuries, which are roughly sketched on a series of anterior, posterior, and right and left lateral diagrams of the body. The section that follows provides a space for the provisional diagnosis, together with three headings denoting the severity of the patient's condition. The immediate treatment occupies a section below this, and consists of a list of modern resuscitative procedures which the surgeon orders by eliminating those not required. Radiographic instructions are provided for, and the succeeding section indicates whether operation is required or not and gives the preferential order for cases to be taken to the theatre. A coloured label is affixed according to whether this preference is (*a*) priority (red), (*b*) early (yellow), or (*c*) delayed (green). This classification has proved to be a great asset in dealing with a ward full of casualties. It is a guide to the radiographer as to the cases to take first and as to the order of their transfer to the theatre. Thus, those with the red label are first to go, being followed by the yellow label cases; the green label cases can usually be left till next morning for operative treatment, the immediate dressings being done in the ward.

Value of a Simple Sheet in Hospital Practice

The advantages of this type of sheet to the various hospital departments can best be shown by a brief statement of how the system works in our own hospital.

Medical.—We have found that a surgical team can, on an average, deal with 25 casualties. The idea of rushing new arrivals to the operating theatre has been generally discarded since the days of Dunkirk, it being realized that methods of resuscitation and procedures to counteract shock are of paramount importance. The surgeon in charge of a group of casualties has therefore adequate time to go the round of his cases, provided the treatment can be clearly indicated with the least possible delay. For this reason copious note-taking at this time must be dispensed with. As will be seen, the subdivisions of the sheet allow fully for this to be done. The surgeon makes his examination and in a few seconds completes the sheet, thereby giving the provisional diagnosis, instruction for radiography, the resuscitation procedures he requires, and the grading of cases for time of operation. He also assesses the degree of severity, which indicates to the clerical staff the procedure which instructions state shall be followed for E.M.S. cases.

The other members of the team follow up and, taking the red label cases first, carry out the ordered treatment which requires their personal attention—for example, intravenous therapy, blood pressure, and haemoglobin estimations. The treatment having been completed the sheet is initialled in the space provided at the side. Thus the surgeon is enabled to look though his own cases and then proceed with the operative work, each patient arriving at the theatre in the correct order and with the preliminary treatment carried out.

Radiography.—It has been found that practically all cases admitted under war conditions require an *x*-ray examination. The radiographer, working with a portable apparatus, takes the cases in order according to the coloured label. He has not to keep asking which to take first; he can proceed unhindered with his work, his instructions having been given in the appropriate column. When the films are completed they are hung at the foot of the bed and go with the patient to the theatre.

Nursing Staff.—Injections ordered are given by the sister, who, with the help of the concise recordings of the sheet, gains a clear and quick conception of what is happening to patients in her ward. Anaesthetic premedication is given, and there is little likelihood of cases being sent to the theatre in the wrong order, thereby delaying treatment of more urgent cases. The minimum amount of clerical work by the nursing staff is called for, their only contribution being the simple details of name and age at the top of the sheet. All other details required by the clerical department are obtained by their own staff.

Administrative Staff.—The amount of details which can be obtained obviously depends on the condition of the patient, but so far as is possible enough are taken to allow for procedures required from the clerical department to be put into motion. These procedures include the provision of data for hospital records, information to be supplied to the Casualty Bureau and Service Departments, completion of M.P.C. 47—which folder is then returned to the ward—completion of Form E.M.S. 105, correlation of total numbers, and, in fact, all statistical information asked for very early in the proceedings. The clerk dealing with the case takes note of the severity of illness and sends out formal notices to relatives in accordance with E.M.S. instructions. When the administrative details have been obtained a special stamp is put on the chart which indicates that the cases have been dealt with; it is thus easy to see which still remain to be attended to. The patient's religion is clearly shown at the top of the form, and the respective ministers of religion can also see at a glance the severity of the patient's condition.

Conclusion

A big influx of casualties is very likely to lead to confusion if a clear-cut system is not established—everyone has his own work to do, and the necessity for questioning by this or that person should be removed so far as is possible. The use of our simple emergency admission sheet has done much to effect this, and the fact that everyone can get on with his own particular task undisturbed leads to a smooth-working efficiency in the hospital organization which must be of direct benefit to the patient.

WELFARE IN THE WOMEN'S SERVICES

The enrolment of women as auxiliaries to the fighting Services on a scale far exceeding that of the last war has introduced many new and difficult problems. Their corps have expanded so quickly that many of their conditions have had to be improvised. Great ingenuity has been shown on all sides, but some units have suffered discomfort and others confusion. The shortage of labour and materials slowed down the construction of accommodation and the delivery of clothing and equipment. Officers had to carry out duties for which they had not been perfectly trained, and severe weather added to the difficulties of everyone. The growing-pains of the movement were reflected partly in definite and well-founded public complaints of bad conditions, and partly in a crop of vague rumours about drink and immorality. The Government wisely determined to apply the remedy of publicity. On Feb. 24, 1942, the Prime Minister appointed a committee to inquire into and report on the amenities and welfare conditions in the three women's Services. The chairman was Miss Violet Markham, and the members included senior representatives of the fighting Services and M.P.s. The medical members were Sir David Munro and Dr. Edith Summerskill, M.P.

The committee's report[1] gives not only a full and fair account of the Services which should effectively dispose of the charges maliciously levelled against them, but lays a firm foundation of knowledge for the future.

The care taken in all the Services to maintain a high standard of health and hygiene impressed the committee very favourably. The members of the committee were assured by the medical officers at the departments and the stations that the health of the women is extremely good. They were struck by the marked improvement which the first month's training effected in the physique, poise, and self-confidence of the recruits. They suggest pertinently that uniform health records should be kept for the Services and for Government establishments, so that the information may be used after the war for a study of health in relation to women's employment. Women in the Services, as in industry, have double the sickness rate of men. The special ailments of women account for part of the increase, but the greater incidence of sickness is among the immobile. The best menstrual health was found among women doing strenuous physical work. The large amount of dental treatment needed was a revelation to the committee.

Reporting Sick: A Criticism

They received a number of complaints of inattentiveness or lack of skill in the medical and nursing staff, and the treatment of minor ailments caused them some uneasiness. It was alleged, for instance, that girls had to get up and attend sick parade even when they felt ill, that waiting rooms were not always provided, and that patients had to wait long in draughty passages. They were also told that the medical officer sometimes neglected to visit a girl ill in her barrack room or her billet. Many of these complaints proved worthless, but others were supported. How far these, when proved true, belonged to the past of pressure and difficulty the committee could not say. In theory a girl who feels ill reports to the non-commissioned officer in charge of her room; the N.C.O. takes her temperature, and if it is above normal the girl remains in bed until seen by the medical officer. Many auxiliaries, however, stoutly denied that this procedure was always carried out. The committee therefore recommends that commanding officers should constantly review sickness arrangements and ensure that the rules are strictly enforced; it should be the special duty of the company officer to see that her sick receive prompt medical attention, and to be especially vigilant when a girl reports sick in billets or on a remote site. The committee is also concerned at the failure to provide special diet for girls suffering from minor ailments. Sausage-and-mash and roly-poly pudding, it declares, though excellent in themselves, may be unsuitable for a girl suffering from a sick headache. It also considers that patients allowed to stay in their own quarters for a temporary indisposition should not be obliged to get up to obtain their food. Medical inspection parades, other than sick parades, are frequent, and are, unfortunately, all the more necessary because of the prevalence of infestation by scabies and head lice. Head infestation has, however, been reduced to less than 2%, as against 25% in the civilian population of comparable age groups.

Need for More Women M.O.s

The committee found the medical personnel and hospital accommodation adequate. The hospitals are well staffed by specialists, including women dietitians, and include well-equipped special hospitals and centres—e.g., for orthopaedic and nervous disorders. Both the Navy and the Army Medical Services have women on their directorates, and a similar appointment is to be made in the Royal Air Force. The committee thought that more women medical officers should be appointed to the A.T.S. and W.A.A.F., especially in the large reception and training centres; that more use should be made of them in the W.R.N.S. reception stations; and that a woman medical adviser should be appointed to each naval command. State-registered nurses and V.A.D.s are employed in the hospitals and large sick-quarters of all the Services; and the committee admired the combined post, just instituted by the R.A.F., of nursing and health welfare sister to act as health confidante to women. The R.A.F. also employ women trained as nursing orderlies to work in the men's hospitals, and the committee suggests that such of these women as show ability and vocation should be given an opportunity to transfer to the nursing profession.

The committee received complaints about hygiene lectures in the Forces. Some of its members heard and approved of the W.A.A.F. lecture, which was given by a woman doctor, but were not satisfied with the conditions under which it was given. Such an address should not, it considers, be given in a large hall to an audience of recruits of all ages. It suggests that a lecture should be given to all three Services on the wider implications of sex behaviour, not because the sex morals of the Forces are more precarious than those of civilians, but because life in the Forces presents new educational difficulties. It finds, however, common agreement that ephemeral sex relationships create more emotional problems than they appear to solve, and it is of opinion that the combined wit of the medical and educational services should be able to provide a standard lecture on broad lines which would be generally acceptable. A set lecture, however, will not go very far on the road of sex education, and the committee thinks that if officers were instructed more fully in the various aspects of the subject they would be better equipped to play a vital part in their dealings with individual women.

---

[1] Cmd. 6384, 1942. H.M. Stationery Office. (1s.)

Pregnancy and Childbirth

"Illegitimate pregnancy is almost certainly, it says, less common in the Services than outside. No woman runs an extra risk of becoming pregnant by joining a Service, and if she does become pregnant the arrangements made for her care and disposal are both humane and efficient. She goes to a discharge depot for a short time, and while there she is put in touch with one of the voluntary societies and other bodies which make arrangements for confinement and the future. The facilities have proved adequate, but the situation is now becoming more difficult as the Services expand. Not only single women need help, for the Services contain numbers of married women with no homes. Here, the committee points out, is a national and not a Service problem. It presses the urgency of this on the Ministry of Health, and suggests immediate action by grants to local authorities and voluntary associations for further accommodation during pregnancy, and by increasing the provision in hospitals, maternity and convalescent homes, and residential nurseries for children. The figures for venereal disease are half those in men's units. Arrangements for diagnosis and treatment are adequate, but more women medical officers might be employed in the gynaecological wards of the hospitals. The committee makes the point that loose behaviour is not necessarily the product of Service life, which generally puts the relations of men and women on a healthy and normal basis. It finds that promiscuous conduct is limited to a small proportion, and that the allegations of immorality which have disturbed opinion reflect most unfairly on an admirable body of women.

The report should not only go far to reassure the public about the conduct of these Services but should serve the valuable purpose of making their organization and problems better known. For the first time in history a vast number of our young women are receiving a regimental training in discipline and arduous communal living. Their present experiences will profoundly affect their whole future attitude to life, and through them that of their children. To ensure to them now the best possible conditions for bodily and spiritual welfare is a vital duty, and the report may make an important contribution to its performance.

Reports of Societies

SYMPOSIUM ON REHABILITATION

At the annual meeting of the British Orthopaedic Association held in Nottingham from Sept. 25 to 26, under the presidency of Mr. G. R. **Girdlestone**, the dominant theme was the present arrangements and future plans for rehabilitation of the injured.

At Harlow Wood Orthopaedic Hospital Mr. S. A. S. **Malkin** demonstrated the work of the hospital's remedial workshops, and a film was shown illustrating the methods employed there and at a special annexe in the occupational reconditioning of E.M.S. casualty patients. Later, at the Rehabilitation Centre for Miners at Berry Hill, near Mansfield, a discussion was held in which the matter was dealt with from the points of view of the surgeon, the employer, the industrial medical officer, and the trade union.

The Surgeon

Mr. E. A. **Nicoll**, opening the discussion, said that the problem was threefold: first, the purely scientific aspect of physical restoration; secondly, the psychological one of obtaining the full co-operation of the patient; thirdly—and sometimes more difficult—the sociological problem of obtaining the proper social context for the conduct of rehabilitation. As soon as injured, every working man's first desire was to get well as soon as possible. It was when delay occurred that doubts and fears crept in. These must be removed, and morale and initiative maintained. Co-operation by the employer, the industrial medical officer, and the trade union had produced, in his experience, a team in which the surgeon played an important part from beginning to end. The result had been the almost complete disappearance of litigation. The statistical difference between a socialized and non-socialized accident service is at least 10%, expressed in terms of men returned to pre-accident work, and that was something very considerable when expressed in the return of workmen to the vital man-power of the country.

The Employer

Mr. Guy de G. **Warren**, as an employer, gave an account of the organization responsible for the development of the Berry Hill Centre. The Midland Colliery Owners' Indemnity Association was formed by a group of associated companies and was concerned to deal with the insurance risks of accident. It was not run for profit and represented the employment of over 100,000 men. With many others, they had been shocked by the state of the treatment of injuries as revealed in the report of the B.M.A. Committee on Fractures. The companies with which Mr. Warren was associated were able, first of all by subsidies, to ensure throughout the area the development of efficient fracture clinics, and this had resulted in an earlier restoration to some working capacity. It was soon appreciated that the lack of facilities for reconditioning prevented men from obtaining full recovery. The job was therefore completed by this rehabilitation centre, and it had been justified from the economic and from the humanitarian points of view. His opinion was that any national hospital scheme must include similar reconditioning schemes. From his experience he thought that one centre capable of dealing with 60 patients simultaneously could treat and discharge approximately 500 cases a year. As it would appear that of accident cases occurring in heavy industries and requiring hospital treatment 20% needed a course of rehabilitation, then one unit would be necessary for a hospital or group of hospitals dealing with about 3,000 such cases annually. On the other hand, the percentage of hospital accident cases other than those in heavy industries needing rehabilitation treatment should not exceed 8%. Therefore one unit should suffice to deal with a group of hospitals admitting 8,000 such cases a year. The workman must be dealt with in an atmosphere where he knew that everyone from the hospital to the employer was out to help. A man admitted to the centre was given the assurance of the surgeons that he could be improved and that work would be available for him afterwards. The growing utilization of industrial medical officers in factories would help to foster greater care for the injured man after his return to industry.

The Industrial M.O.

Dr. Donald **Stewart**, speaking as an industrial medical officer, said that at present the position of production was paramount. It was being somewhat retarded by absenteeism, partly due to injury and sickness. Injuries were increasing, important factors being the amount of new and unskilled labour drafted into industry, often working under overcrowded and other difficult conditions. There was therefore overloading of the casualty and out-patient departments of hospitals in industrial areas, which had to carry on with diminished staffs and with difficulties in obtaining equipment and materials. There was thus a challenge to hospital services and the medical profession to see that an adequate service was maintained for people in production. Some particular problems were provided by young persons in industry, married women, and accidents at night-time and on Sundays in the factories working then. The industrial medical officer had an important function to perform, first of all in the general supervision of the conditions of work, and of measures designed to prevent ill-health and injury, the initial treatment of accidents, the follow-up of patients who could stay at work and of those who returned after-treatment and rehabilitation. He was the one person who could interpret the wishes of the surgeon because of his knowledge of the conditions of work and the types of job available. There must be a steady improvement in the initial treatment of injuries. The sepsis rate was high, and insufficient care was taken of so-called minor injuries. In 1,000 consecutive accidents in one factory he had found that 52% were finger injuries only. Incapacity rate was great because they were not treated with the seriousness due to them. One big problem was to provide an adequate service for the treatment of injuries in small factories which could not have their own medical units. In Birmingham, in order to meet that difficulty, they had proposed the provision of a travelling surgical unit, thus taking the hospital to the factory for the more serious injuries, which should be dealt with in the initial stage on the spot.

The Trade Unionist

Mr. J. L. **Smyth**, speaking from the trade union point of view, felt that more should be done to prevent accidents by ensuring proper selection of personnel so that people did not work on jobs for which they were unfitted. He made a plea for a greater understanding of each other's job as between the doctor and the workman. The ignorance of the doctor about working conditions was often responsible for much misunderstanding, particularly as it referred to certification under the Workmen's Compensation Act. At the same time the workman undoubtedly very often misunderstood the doctor's position. The doctor could do much to remove the prejudices of the less enlightened, among both employer and employed. He felt that the industrial doctor might be handicapped because he was himself an employee of the firm. His job, however, was to serve the workers, and probably he would himself prefer to be altogether independent of the management. Mr. Smyth deprecated the controversies arising in the courts between the individual worker and employer with lawyers and doctors ranged on either side to fight the matter out, which gave no satisfaction to anybody. The trade unions were delighted to have been associated with the development of the idea of rehabilitation centres such as had been outlined by Mr. Watson-Jones. Those centres already in existence had furnished practical demonstration of the value of the idea. The T.U.C. had recently given approval to the idea and called upon its general council to demand that the Minister of Health bring about an intensive development of this service, which would include mobile medical units. The compensation bogy must be destroyed. He would like to see standardized records at all hospitals and the preservation of continuity of treatment, and to see doctors in hospitals working closer together in a common policy on behalf of the nation with the resources of the country behind them.

General Discussion

In the discussion afterwards Sir **Walter Citrine** remarked on the big element of conservatism to be overcome on the part of both the medical profession and the workman. He felt that there was no place for the consideration of economic motives. Their noblest aspiration should be by skill and organization, whether in hospital or rehabilitation centre, to restore humanity and take away the disability produced by accident. Trade unions were willing to co-operate with anyone, whether employers or social agencies, if they were imbued with those high humanitarian ideals. Mr. G. **Perkins** of Roehampton emphasized the need for starting the work of reconditioning from the initiation of treatment in hospital and said that the work should be supervised throughout in both hospital and centre by the surgeon in charge of the case. Mr. R. **Watson-Jones**, of Liverpool said it was just as important to avoid the fear and litigious atmosphere that might develop after injury as it was to avoid non-union of a fracture. Every fracture surgeon must be more than a craftsman: he must be a psychologist. The newness of the idea of rehabilitation was only in putting forward the psychological aspect so prominently. The British Orthopaedic Association deserved credit for its work in promoting fracture clinics and rehabilitation centres. The latter must not be a counterpart of the old massage department of hospitals. They must be geographically separate, with the advantages of open air, freedom, and separation from the hospital atmosphere. The problem to-day was far more than economic or humanitarian. This country was at war, and it was vital that every man should be back at work.

The **President** emphasized the important part played by Sir Robert Jones in the whole development of the idea of rehabilitation. It was he who in the last war had insisted on the value of active co-operation of mind and limb in the restoration of movement in stiff joints and in the restoration of muscle power and co-ordination. At the workshops at Shepherd's Bush Sir Robert showed what could be done for the reconditioning of the disabled. The tragedy was that so much of his teaching in this direction had been allowed to slide in so far as it affected the treatment of accident cases throughout the country.

In the course of the meeting a series of clinical papers were read and demonstrations given at the Harlow Wood Orthopaedic and Nottingham General Hospitals.

Those who made contributions were Mr. A. M. **Birkett** of Nottingham, Mr. R. G. **Pulvertaft** of Grimsby, Mr. J. P. **Campbell** of Nottingham, Mr. J. **Grocott** of Stoke-on-Trent, Mr. J. **Hardman** of Sheffield, Mr. L. H. **Morris** of Leicester, and Mr. S. A. S. **Malkin** and Mr. F. **Crooks** of Nottingham. Interesting groups of cases were demonstrated at both of the hospitals.

Correspondence

Tuberculosis and Milk

Sir,—The recommendation of the M.R.C. Committee on Tuberculosis (Oct. 10, p. 436) that "the pasteurization of milk should be extended throughout the country, and, where this is not practicable, all milk consumed by children should be boiled," has during the past 10 or 12 years been repeatedly urged by the People's League of Health, the Joint Tuberculosis Council, the Royal College of Physicians, and the British Medical Association. In spite, however, of this weight of authority the advice has had but a limited application. For this failure two reasons may be suggested. One is that the reports of scientific councils do not much engage popular reading; and the other, that the public is misled by such alluring titles as "clean milk," "pure milk," "accredited milk," and the like, and does not realize that none of these labels affords any protection against the risk of tuberculosis and other infections.

May I repeat the suggestion that where learned corporations have failed the individual doctor may readily succeed. Parents and the guardians of children, informed by their trusted medical advisers of the true position, would develop a public opinion that would demand "safe milk"—that is, "pasteurized milk"—and the fancy labels of the commercial advertiser would lose their unwarranted appeal. Further, in such an educational campaign medical practitioners would find a welcome opportunity in the practice of preventive medicine, and would discharge a responsibility that falls on the medical profession as guardian of the public health. What is spoken by trusted voices in thousands of homes is likely to have a wider and more immediate effect than many archives. The reward is promised in the words of the M.R.C. Committee: "If all milk for human consumption were pasteurized it is no exaggeration to say that tuberculosis of bovine origin would be eliminated."—I am, etc.,

Hove, 3. C. O. Hawthorne.

Classification of Nerve Injuries

Sir,—I am relieved to find that others than Dr. Russell Brain and myself feel their sensibilities disturbed by the neologisms that Prof. H. J. Seddon proposes to add to the already florid vocabulary of neurology. The subject must soon become totally unintelligible to all but those primarily concerned with it if this passion for diving into the lexicon is not checked. I will not here reiterate all the arguments I have already privately poured into Prof. Seddon's insentient ear against his adoption of this set of ill-sounding triplets, though I continue to wonder how he does not realize that the illimitable resources of our mother tongue are adequate to convey ideas and to state facts far more subtle than those presented by nerve injuries. Working as he does in Oxford, it is sad that Prof. Seddon is not willing to fight for the lost cause of English in medical terminology.

However, it appears that what seem to him the needs of a precise and unequivocal nomenclature require that he shall adopt these specimens of tortured Greek, made to serve a purpose for which they were never intended, and all I am now venturing to ask is how it comes that with standards so exacting he has allowed himself to adopt the term "fibrin suture" (*Lancet*, July 25, p. 87) for the method of sticking together the two ends of a severed nerve by a few drops of plasma. "Suture" we all understand to mean stitching, and the *O.E.D.* informs me that it refers to the "joining the two ends of a severed nerve or tendon by stitches." "Fibrin suture," as he uses it, might perhaps pass as a rough workaday term were it not that Prof. Seddon has burst upon us as a terminological purist, ready to affront our ears and to shame our unfamiliarity with ancient Greek in the name of scientific precision. As I "gum suture" my stamp to the envelope that is to carry this letter to you, Sir, I wonder how Prof. Seddon will explain away his lapse from consistency. But I suppose that when even Homer nods another Greek writer may do the same without reproach.—I am, etc.,

London, W 1. F. M. R. WALSHE.

Crush Syndrome

SIR,—Following the demonstration of a "crush-kidney" syndrome in dogs,[1] research of a similar nature has been continued on cats (under nembutal or chloralose anaesthesia), during the course of which one fact of possible practical significance has come to light.

If the hind limbs are bound sufficiently tightly with rubber tubing to become completely ischaemic, as evidenced by reduction of foot temperature to that of the surrounding air, sudden release after 3 to 4 hours results in considerable impairment of renal function. In 11 such animals the average fall in creatinine clearance following this procedure was 51% (varying from 26 to 78%), although oliguria was prevented by infusion of sulphate-saline solution and blood pressure restored with gum-saline. In 7 animals in which the tubing was not tied sufficiently tightly to produce this degree of ischaemia an average fall of 24% (varying from 14 to 35%) in creatinine clearance resulted. If, however, the circulation is readmitted to such limbs gradually, no appreciable impairment of renal function can be observed. In 10 animals treated in this way the average change in creatinine clearance was +1% (varying from −9 to +16%). In one other, which was suffering from jaundice, a drop in clearance of 33% was noted, and later experiments on eviscerated animals suggest that the liver is responsible for detoxicating the blood coming from the ischaemic muscles, if sufficient time is allowed.

The process of gradual re-establishment of the circulation in the limbs is simple in the cat owing to the extreme richness of arterial anastomoses. Before untying the limbs, the aorta is clamped immediately above the bifurcation—i.e., below the lumbar arteries. After half an hour, with occasional gentle massage of the limbs, the femoral artery is clamped as high as possible and the aorta released. By this time the thigh has warmed up appreciably and the main vessels are full of blood. After a further half-hour, again with occasional gentle massage of the muscles, the femoral artery is released and full circulation thus established. Such a procedure is clearly out of the question in human casualties, but the same end-result might well be achieved in suitable cases by less drastic means.—I am, etc.,

University College, Leatherhead. M. GRACE EGGLETON, D.Sc.

Crush Injury and Anoxia

SIR,—In my letter on crush injuries (July 26, 1941, p. 139) I endeavoured to establish that, as suggested by Sir L. Hill (1941), the renal characteristics of the "crush syndrome" were due to *anoxia* following traumatic shock. From your columns it is evident that the belief is widely held that the crush syndrome is due to some obscure and still unidentified toxic derivative of crushed or necrotic muscle or tissue. The following considerations, however, militate strongly against such a belief.

1. According to Bywaters and Beall themselves (1941) the renal damage in cases of crush injury appears early and is progressive even though the crushed limb be amputated.

2. It is not possible to establish by cross-circulation or other methods that the blood of an animal suffering from traumatic shock (crushing of the limbs) is toxic (McDowall, 1940).

3. The characteristic degeneration of the epithelium of the renal tubules in crush injury is not found in infarction or absorption of blood clot (tissue necrosis).

4. The renal degeneration met with in crush injury is found in cases of injury where no crushing of muscles has occurred (Mayon-White and Solandt, 1941; Glen, 1941; Young and McMichael, 1941).

5. A condition similar to the renal failure of crush injury with similar degenerative changes in the convoluted tubules is found in the anuria of cholera persisting after successful restoration of the circulation by saline transfusions (Tomb, 1942).

In addition to the foregoing considerations it is to be observed that the fall in blood pressure which often follows the release of a tourniquet from an injured limb is not due to the liberation of toxins from the injured area, as is often assumed, but to the sudden enlargement of the vascular bed (McDowall, loc. cit.), associated no doubt in many instances with diminished blood volume due to incipient shock.

Anoxia may be produced, apart from circulatory defects, (1) by obstruction to breathing of the normal atmosphere (from strangulation, drowning, pneumonia, asthma, etc.); (2) by diminution of the oxygen content of the inspired air (as at high altitudes or in respiration chambers), and by its replacement by other gases such as CO_2, CO, CH_4, N_2O, etc.; (3) by diminished oxygen-carrying capacity of the blood (*a*) from the replacement of oxyhaemoglobin by methaemoglobin, carboxy-haemoglobin, or nitric-oxide haemoglobin, (*b*) from diminished blood volume (as in haemorrhage, collapse from cholera, and traumatic shock), (*c*) from diminished total haemoglobin content of the blood (as in hypochromic anaemia, haemolysis, and pernicious anaemia). In this connexion it is of special significance to note that Bywaters and Beall (loc. cit.) report that renal changes very similar to those met with in crush injury are found with anuria in cases of haemolysis due to incompatible blood transfusion ("transfusion kidney"). Similar degenerative changes of the renal tubular epithelium with anuria are also found in blackwater fever (Manson-Bahr, 1935) and in pernicious anaemia (Leftwich, 1920; Stieglitz, 1924), the common factor in all these cases being anoxia due to anaemia consequent on haemolysis or defective blood formation.—I am, etc.,

Splenectomy in Purpura Haemorrhagica

SIR,—Dr. Bruce Williamson (Oct. 3, p. 407) castigates Prof. Witts for his "levity" in advising splenectomy in purpura haemorrhagica. On Dr. Williamson's own admission he (with the late G. A. Sutherland) was responsible for the introduction into this country of splenectomy for this condition (1925). In 1926 in a paper "Recent Advances in the Diagnosis and Treatment of Purpura Haemorrhagica" (*Archives of Disease in Childhood*, 1) he states in regard to splenectomy for this disease: "The results are so uniformly good that it appears to be only a matter of time before this disease is classified as curable by splenectomy. The results are comparable with those of splenic anaemia and acholuric jaundice."

In 1928 in my monograph *Acute Aplastic Anaemia* (p. 28) the following appears:

> "The disease which bears Werlhof's name is really a conglomeration of diseases which have one condition in common—deficiency of platelets. There is only one of these conditions—thrombocyto*lytic* purpura—in which splenectomy is indicated, and unless evidence of destruction of platelets by the spleen is demonstrable splenectomy is contraindicated. Bruce Williamson, in a review of the literature of sixty-five cases of splenectomy for this condition, makes no mention of the thrombocytolytic character of the disease, nor does he mention the importance of considering the complete blood picture before deciding in favour of splenectomy. This is a serious omission in a paper bearing the title 'Recent Advances in the Diagnosis and Treatment of Purpura Haemorrhagica.' An analysis of the deaths amongst the cases cited by him suggests that the culpability of the spleen was not sufficiently established prior to operation."

---

[1] Eggleton, Richardson, Schild, and Winton, *British Medical Journal*, 1942, 2, 392.

During the 16 years which have elapsed since Dr. Williamson unreservedly advocated splenectomy as the ideal treatment for this disease I know of no publication by him in which he confesses his conversion to the views expressed by me in 1928. It is hardly fair of him, therefore, to deal so severely with Prof. Witts, who, in recommending splenectomy in his two cases of thrombocytopenia, was supported by the authority of the physician who introduced the operation into this country—Dr. Bruce Williamson.—I am, etc.,

A. Hayes Smith, M.D.

Trichlorethylene as General Anaesthetic

Sir,—The letter from Drs. Lloyd-Williams and Hewspear (Aug. 8, p. 170) recording fibrillation in a patient with non-toxic goitre under trilene anaesthesia has stimulated valuable comment from two of your readers. At the Royal Free Hospital we are constantly on the look-out for improvements, and it is the policy of the anaesthetic department to follow up every constructive suggestion offered to it. We are therefore grateful to Dr. Langton Hewer and Dr. Newton Price for their letters. May I say a few words in explanation of some of the methods we have adopted.

Intubation: While we are aware of the vagal reflexes which physiologists have told us can occur when the bronchial mucous membrane is insulted, it is possible to say that in more than 15 years, with an average of between 300 and 400 anaesthetics for thyroid operations a year, neither my colleagues nor I have seen any evidence of their existence. This may be due to the fact that our cases are "cocainized." It has often been said to us that thyrotoxic cases should not be intubated because without endotracheal tubes they can be maintained in a lighter plane of anaesthesia. With a moderate degree of cocainization and blind intubation this is not true; but because of such suggestions we have many times, for considerable periods, anaesthetized cases without intubation, only to return (often at the surgeon's request) to the original method. So far as possible we use only first-plane anaesthesia, but always with ample oxygen; our experience is that the complete freedom of airway, lack of anoxaemia, and good condition of the patient (checked in every case by blood-pressure readings) amply justify the method.

Novocain and adrenaline: We aim at a method of true anoci-association and regard the effect of the novocain as an important part of the anaesthesia. Except in those patients whose Goetsch test is positive, we have seldom found that a strength of 1/150,000 adrenaline has any effect on the pulse. In some cases which we infiltrated with adrenaline without novocain the skin incision and dislocation of the gland often produced reflex movement.

Dr. Newton Price's letter raises an interesting point. Premedication for thyrotoxic patients is always a difficult problem. For nearly a year we have been trying chloral hydrate in place of the more usual basal narcotics. So far we have used it in about 300 cases, and it seems to be satisfactory. Patients come to the theatre awake but in a condition which can best be described as "placid." A further communication on this subject is intended at a later date.—I am, etc.,

Stanley Rowbotham,
Major, R.A.M.C.

Shock Treatment in Psychiatry

Sir,—In your leading article (Oct. 3, p. 397) on shock treatment in psychiatry you rightly stress the importance of the early diagnosis and treatment of schizophrenic and allied conditions.

It appears a pity that shock treatment, like many other modes of treatment which have made a sensational entry into the medical world and have been abused by lay literature and press, is in grave danger of being used too indiscriminately, and thereby the value and the reputation of this mode of cure are liable to suffer. Many cases, unsuccessful because of unsuitable selection, will finally lead the practitioner and even the mental specialist to regard the treatment as useless, and thereby many cases really suitable will be robbed of their only chance of recovery.

I think we have to divide all cases suitable for shock treatment into two groups, the basis of division being the aim of the treatment. Shock treatment includes both insulin and convulsion treatment. Group 1 includes early cases of schizophrenia treated with some hope of complete recovery, or at least of keeping initial and slight symptoms stationary for many years. Group 2 includes all cases, early or those for which there is little or no hope of recovery or even prolonged remission; the treatment is purely symptomatic in aim.

Suitable for the first group are only very early cases—i.e., the treatment is begun within the first year of certification, or preferably at a time when a young person, though not yet requiring certification, shows definite signs of introversion and a progressively deteriorating schizoid personality. Unfortunately the present system of certification makes it practically impossible to get at these cases early enough, as the certification is naturally postponed until the illness is far advanced, and hardly anybody can be persuaded to enter a mental hospital for early treatment, even voluntary, in such early stages of the disease because of the stigma still attached to these places. It is therefore high time that general hospitals should open wards for the treatment of such early cases and not only dispensaries and observation wards. Such patients could then undergo successful treatment without being stigmatized for the remainder of their life.

In the selection of these cases it is important to consider the type of illness, the best prognosis being in acute katatonic cases with no family history and no background of mental deficiency. Gradually developing hebephrenics, unless treated very early, show little recovery. Many cases of confusional excitement which are actually incipient schizophrenics have a very good prognosis, and the argument of some critics that one will treat thereby many cases which would have recovered also spontaneously is not valid, because even a few cases of schizophrenia thus nipped in the bud will mean much to humanity.

As to the second group, it will have to be explained to the relatives that a complete cure is not hoped for but the patient will show some improvement. Some cases of acute katatonic excitement may thus be brought to rest, stuporous patients often become more amenable to nursing, and patients refusing their food will soon eat spontaneously. I would include in this group all advanced melancholics and involutional melancholics, which, though not schizophrenic, are often treated by convulsions. The results are in these cases usually only symptomatic.

It seems to me that these points must be kept in mind when selecting cases for shock treatment, and much disappointment will thereby be avoided.—I am, etc.,

Abergavenny. K. A. Graf.

Sulphonamide Sunlight Eruptions

Sir,—I read with interest the article on sulphonamide sunlight eruptions by Capts. R. G. Park and W. M. Platts (Sept. 12, p. 308). I feel, however, that some at least of their cases are capable of a different explanation from that given. After any considerable sunburning of the skin the capillaries of the sunburnt areas tend to dilate more readily than those of normal areas, even after the obvious signs of sunburning have disappeared. This undue reactivity of the capillaries shows up whenever the patient develops a widespread erythema, which will be more obvious on the previously sunburnt parts, and it can easily be demonstrated by a hot bath. I therefore suggest that some of the cases recorded are not due to a true actinic sensitization but are merely an ordinary sulphonamide rash appearing most conspicuously on areas previously affected by the sun. I make this suggestion for the following reasons. The eruption usually appeared about the eighth to the tenth day, the usual time for an ordinary sulphonamide rash; in many cases unexposed parts were also involved, which is very uncommon in actinic dermatitis; some patients developed the rash even though they were not exposed to the sun after taking the drug; the sensitivity disappeared in two to four days, which is more rapid than in other types of actinic dermatitis such as that from eosin.

While fully admitting the possibility of sensitization of the skin by sulphonamides, I feel the diagnosis should only be made after due regard to these considerations lest these drugs gain an undeserved evil reputation.—I am, etc.,

F. F. Hellier,
Major, R.A.M.C.

Nomenclature of Night-blindness

Sir,—We must all feel grateful to Dr. John Ware for his historical and classical contribution (Oct. 3, p. 409). His suggestion of "nyctamaurosis" and "nyctamblyopia" is reasonable if it is really necessary to have two substantives to indicate different degrees of blindness; but "complete" and "partial" seem to fill the bill pretty well. My preference for "nyctamaurosis" over "nyctamauroma" is based on the desire for consistency (or even logic) with its lightening of the tax on our memories. However it may have been in old times, it is indisputable that for many years past new words ending in "oma" have all indicated a tumour, either of a definite character or in a definite situation; their name is legion. On the other hand, whenever we have wished to indicate a process, general condition, or infestation we have invariably applied the termination "osis"; the most up-to-date example is, I think, "avitaminosis." It is true that there are a few "omas" (or "omata") which are not indicative of tumour formation, but they are so few that they can be easily remembered as exceptions to the rule. Why tax our memories with another exception (and perhaps more to follow) when by playing the game according to the modern rules we could play it almost with our eyes shut?—I am, etc.,

Ambleside. J. Price Williams.

Sir,—It would almost seem that some telepathic influences have been at work, for Dr. John Ware (Oct. 3, p. 409) has travelled along the same mental path that I have trod, even to realizing more fully that our English language is far from being absolute. Purblind, nearly blind, short-sighted: (orig.) wholly blind, is an excellent example. Dr. Ware goes the length of agreeing with me that *oma* may indicate something concrete or it may not.

"Nyctalopia" and "hemeralopia" we unanimously abandon, but we reach different destinations. To reach his he is willing to put a new meaning into the established words "amaurosis" and "amblyopia," the former meaning for him "complete loss of vision without qualification"; the latter, "partial loss of vision without qualification." In other words, we are asked to put new wine into old bottles. If we attempt this the bottles will break and the wine run out. I prefer to use two new words, "nyctamuria" and "nyctamauroma," for in doing so I put new wine into new bottles and both shall be preserved.—I am, etc.,

London, W.1. Francis E. Preston.

Sedimentin Index and Sedimentation Rate

Sir,—May a hard-worked general practitioner raise his small voice in this controversy? Dr. P. Edwards and Mr. L. J. Cuttrill, writing from Market Drayton Sanatorium (Sept. 26, p. 379), have stated *ex cathedra* that "any test should be as simple as possible and give the maximum of reliable information"; the more I study this statement the less sense can I make of it. I think I know what they mean; but even so, it isn't true. From what little I have seen of sanatorium practice I have long since come to the conclusion that in the world of tuberculosis tests, which began life by being simple, tend with the increase of knowledge and experience to become more complex in technique. For example: (1) Temperature-taking ceases to be a matter of thrusting a thermometer under the tongue for a roughly guessed minute (or, simpler still, of laying the hand upon the brow), and becomes a ritual wherein the patient lies completely relaxed for half an hour before warming the thermometer for two minutes in his rectum. (2) *X*-ray examination ceases to be a matter of snapshots, and now involves in addition lengthy and careful screening of each area of the lung field and mediastinum with the patient twisting this way and that. To make it more effective the radiologist has to spend some valuable time beforehand in the dark in order to accommodate his eyesight. (3) Sputum examination, too, it seems, is no longer entirely a matter of a stained smear, but involves concentration, culture, and animal inoculation. I will refrain from drawing the obvious conclusion, and merely condole with all sanatorium physicians (especially those at Market Drayton) that so much of their leisure should be encroached upon by these time-consuming "refinements."

May I now presume to contribute my personal experience of the blood sedimentation test from the G.P.'s point of view? I started determining sedimentin indices in general practice just over a year ago, and soon found not only that the information I derived from them was more useful than that given by the Westergren readings, but also that the procedure was actually less bother. You see, neither I nor my dispenser could be guaranteed not to forget—or, if we remembered, not to be otherwise involved—when the exact moments came round to take the hour-readings; whereas with the rack of six tubes on my (or her) desk it is the simplest matter to note the different "falls" every ten or fifteen minutes between, and even during, consultations. On my round of visits I have on the car floor the rack of bloods taken from bed patients, so I can note and record the "falls" every time I stop the car, and again just before I proceed on my way. This takes less than twenty seconds; I know because I've timed it. I can't help feeling that Dr. Clarke Penman (also writing from Market Drayton) is exaggerating when he complains that it takes five times as long as the Westergren readings and that the observer cannot "settle to any other work." Why, with my own eyes I have seen a sanatorium physician with his rack of tubes in the operating theatre, taking readings between refilling his patients' A.P.s. No. The chief obstacle to index determination, I think, is having to look up the logarithm of a number in a book of log tables. So many of us have forgotten how to do it, and so few have the meekness to ask our children.

By means of the sedimentin index it would seem, although I may be mistaken, that not only can one ascertain whether a patient is suffering from a destructive disease process, but that one can *measure* (in a new sort of way) *how ill* it is making him. A series of weekly or monthly determinations reveals the patient's rate of progress, and enables one to forecast with some accuracy how long it will take him to get well again—if he continues to progress at the same rate. It also shows you whether your treatment is making the slightest difference to his rate of progress. This information is not revealed by the first-hour Westergren technique—or even the second-hour. But of course I should no more dream of bringing the Westergren technique into disrepute than I would the taking of mouth temperatures or *x*-ray snapshots. And no less.—I am, etc.,

Norfolk. Rural Practitioner.

"Silent" Sinusitis

Sir,—Mr. Edward D. D. Davis (Oct. 10, p. 441) states that sinus disease as a cause of visual disturbances is very rare, and then quotes 54 cases of retrobulbar neuritis of which only 5 (or 9% of the total) were, in his opinion, of nasal origin. These figures suggest to me that sinusitis should be classed as a common cause of retrobulbar neuritis, not as a very rare cause.

Mr. Davis then goes on to make the extraordinary statement that to the honest rhinologist silent sinusitis does not exist. If by silent sinusitis Mr. Davis means the type of infective and allergic origin to which I referred in my letter (Aug. 22, p. 230), then I resent very much his implication, not in its application to myself, as I am not a rhinologist, but in the application to several of my rhinologist friends, who, even if they do differ in their views from Mr. Davis, could never be anything else but honest. Dr. W. Edwards (p. 441) remarks that the proof of the pudding is in the eating, and if silent sinusitis does not in point of fact exist, how does Mr. Davis explain the fact that every case of migraine which I have treated has been considerably improved, if not in fact cured, by ephedrine replacements?—and this applies to many cases which have been investigated, with negative findings, by rhinologists.—I am, etc.,

Alderley Edge, Cheshire. J. J. Craig.

Sir,—The letters of Mr. Terence Cawthorne and Mr. Edward Davis lead one to think that they view the success of the practice of medicine only from the point of view of the suffering patient. It is incredible that consultants can be so far out of touch with the times in which we live. Even in Hogarth's time it was said: "The ancients tried to make medicine an art and failed; the moderns have tried to make it a trade and succeeded."

Recently I took under my care a case of certified insanity, within seven days of the time when the patient was to undergo two operations for silent sinusitis, each operation carrying a surgeon's fee of 100 guineas. The patient had never at any time had signs or symptoms of sinusitis. Transillumination, radiographic examination, and culture of antral wash-outs gave negative results. The surgeon who had advised the operation further stated that it was typical of such cases of silent sinusitis that no alteration was to be found in either the B.S.R. or the differential white cell count. This disease, though insidious, is apparently diagnosed with ease by the typical absence of all evidence of disease in the sinuses.

The patient made a complete recovery without surgical interference, which, however fortunate for the patient, might be regarded as less fortunate for the surgeon. Certain organic nervous diseases, abnormal mental states, rheumatic conditions, and pulmonary diseases, to mention but a few, are typically remittent in their course, and obviously offer a fruitful field for the invocation of treatment for silent sinusitis.—I am, etc.,

London, S.E.24 KENNETH MCFADYEAN.

SIR,—Mr. Terence Cawthorne (Sept. 26, p. 379) appears to want to minimize the value of the communications made by Dr. Rosa Ford and Dr. J. J. Craig. No one wishes to operate on healthy nasal accessory sinuses, but his letter conveys the suggestion that these two workers have done so. Perhaps Mr. Cawthorne would describe the radiological evidence which he considers sufficient on which to class sphenoidal and ethmoidal sinuses as healthy or diseased. Would he require proof puncture also in the case of these sinuses; if so, what method does he consider sufficient to demonstrate disease in these sinuses?—I am, etc.,

Powick, Worcester H. F. FENTON.

SIR,—I find Miss Rosa Ford (Oct. 10, p. 441) crossing swords with Mr. Terence Cawthorne over his criticism of slack diagnosis of sinusitis. We are asked to alter our canons of paranasal diagnosis on the evidence of two cases, now somewhat hoary. In the face of this evidence it is surely pertinent to ask why we should alter our customs. It is my view that the so-called evidence contained in these cases amounts to no more than evidence of loose thinking.—I am, etc.,

Newcastle-upon-Tyne F. MCGUCKIN.

SIR,—Long experience has taught me the truth of Mr. E. D. D. Davis's statement that for the rhinologist "silent sinusitis" does not exist. In the two cases of which I gave details in the *Journal* (Aug. 1, p. 128) "silent sinusitis" did not exist for any of the four rhinologists concerned. In consequence both patients were obliged to suffer desperately from headaches for at least 7 years. Such helpless suffering is very prevalent, and would be quite needless if the silence in which sinusitis can wrap itself could be broken, either by such means as Mr. Davis advocates or by those I have suggested, which seem to me simpler and more widely applicable.—I am, etc.,

London, W.1 ROSA FORD.

⁂ This correspondence is now closed.—ED., *B.M.J.*

"Female Circumcision" among the Kikuyu

SIR,—"Female circumcision" as it exists among the Kikuyu (Kenya) is an operation which varies in severity, some sections of the tribe practising a more drastic form than others. The following is a generally accepted description of the "major" operation:

> "It involves the removal of not only the clitoris, but also of the labia minora and half of the labia majora, together with the surrounding tissue, resulting in the permanent mutilation affecting the woman's natural functions in micturition, menstruation, and parturition, with disastrous results not only to the birth rate, but also to the physique and vitality of the tribe."

The so-called "minor" operation is that of clitoridectomy, now adopted by some sections of the tribe as the result of advice and pressure from Government. The missionaries, many of whom are medical men, and nurses have spoken of "the sexual mutilation of women" as being a more correct term than "circumcision." Besides the severity of the operation, and its effects—physical and psychological—on the girls at puberty, bleeding is often profuse at the time of operation and sometimes leads to death. There is always extreme inflammation and extensive cicatrization of the parts affected. Afterwards, normal menstruation is interfered with and sometimes coition prevented. It is significant of the frequency of this result that the Kikuyu have a special word to denote it—"nduri." Plastic operation to relieve this condition is of frequent occurrence in mission hospitals. The most disastrous results of the operation occur at times of childbirth, especially with primiparae. Labour is always delayed and mother or child, or both, often die in consequence of the unfavourable conditions caused by the operation. When mission hospitals were established it was found necessary to make incisions, sometimes several, in order to enable a child to be born.

As the result of a strong stand taken by some of the missions working among the Kikuyu from 1916 on, many Christian girls are now saved from this operation, and thus in certain areas the custom is becoming a thing of the past.—I am, etc.,

Dunbog, Newburgh, Fife JOHN W. ARTHUR, M.D.

Woman-power and Maternity

SIR,—I should like to draw attention to the fact that in your report of the National Conference on Maternity and Child Welfare (Oct. 3, p. 404) reference is made to maternity legislation in Germany and Japan, while the notable achievements of our Soviet ally in this respect are completely ignored. We can find much assistance in the solution of the problems of woman-power and maternity by reference to the special measures which have enabled the women of Soviet Russia to play such a large part in the development and in the defence of their country.

Every pregnant mother in the Soviet Union in peacetime is entitled to a minimum of 56 days' maternity leave before and after confinement (reduced to 36 days before and 28 days after during the war). This is extended to cover half-hour periods every 3½ hours during the nursing period, and subsequently such time as may be authorized by the child's doctor in respect of any illness on the part of the child. Maternity leave is on full pay, and these extensions of maternity leave entail no deduction from the mother's normal salary. Furthermore, on registering at an ante-natal clinic she is entitled to various privileges, such as transference to lighter work if she is on heavy work, and exemption from any night work. Production of her ante-natal card also ensures an expectant mother priority in other spheres, such as shopping and transport.

These are the special provisions of immediate interest to us in the welfare of the pregnant woman in industry and the essential services. There are many others, and those who are interested will find a more detailed account of maternity legislation and the work of the scientific institutes for the protection of mother and child in Prof. Sigerist's book *Socialized Medicine in the Soviet Union*.—I am, etc.,

Southall JOAN K. MCMICHAEL.

Medical Planning Now

SIR,—Owing to wartime difficulties the proceedings of the A.R.M. have been reported rather briefly, and as the result I believe certain important points which greatly impressed the meeting have been lost sight of.

I had previously believed that we would serve our colleagues in the Services best by making no changes in their absence and arriving at no final decisions until they return. And this has been the view expressed from time to time by correspondents in the *Journal*, who feel that we ought to safeguard the interests and future of our absent colleagues. But at the A.R.M. a most striking speech was delivered by a member who stated that he was in the Services, having left his practice to join up. He said that he had taken advantage of a period of leave to attend the A.R.M. I regret I do not remember his name, but from the brief summary in the *Supplement* of Sept. 19 (p. 31) I think it may have been Dr. W. E. Dornan of Sheffield. He appeared to have no illusions about politicians. He urged us on behalf of those absent in the Services to make our plans now, and carry them into effect while our bargaining power was high and before over 10,000 doctors were suddenly thrown on the labour market by post-war demobilization, thereby practically destroying our bargaining power, a situation he expected the politicians to exploit to the full.

I had not realized this obvious danger, and I feel sure that many doctors do not fully appreciate it. Therefore it seems to me advisable that the fullest publicity within the profession should be given to pointing out this risk, in order that measures may be adopted to prevent it.—I am, etc.,

Hove. H. J. MCCURRICH.

Post-war Planning and Winning the War

Sir,—Your issue of April 11 has just reached me and I have read the letter of Mr. R. Watson-Jones with interest. Surely he is right in suggesting that too much time may be spent now in discussing the post-war organization of medicine. Is it not better for the profession to concentrate on maintaining and increasing our war effort? And is it not also clear that any new arrangements should only come into existence when those of us now abroad have had time to come home, look round, and give our considered opinions in a calmer atmosphere than is now possible? The profession has had many unfortunate experiences of high-handed and arbitrary action by Government. The liveliest resentment will be felt if, on our return home, we are presented with a professional situation we dislike and in the shaping of which we have had no voice.

I suggest that the B.M.A. should secure a pledge from the Ministry of Health that no major changes affecting our livelihood will be allowed until most of us serving temporarily with the Forces abroad have been able to return home and look round. After all, we are supposedly fighting for a charter which is to free mankind (doctors included) from arbitrary action by the State or any other powerful authority. Having seen hospitals used as vote-catching machines I would urge that politicians be given no control in any future scheme. They are the last to remember that in a properly conducted profession or service those in control should extend their loyalty to the subordinates below—without which no proper loyalty to those at the top is possible.—I am, etc.,

G. C. Pether,
T/Major, R.A.M.C., Middle East Forces.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

On Friday, Nov. 13, Prof. Major Greenwood, F.R.S., will give a lecture on "Origins of the Scientific Study of Population," and on Friday, Nov. 27, Dr. H. P. Bayon will lecture on "Disease as a Determining Factor in War." Both will be delivered in the lecture theatre at the Arts School at 8.30 p.m., and they are open without fee to all members of Cambridge or London Universities or of Girton or Newnham Colleges.

At a Congregation held on Oct. 1 Dr. J. A. Venn, President of Queen's College, resigned the post of Vice-Chancellor and was readmitted for the year 1942-3. In the course of his address reviewing events of the past academic year Dr. Venn announced that the Rockefeller Foundation had again continued its grant of £1,200 for research in cellular physiology at the Molteno Institute, and is providing £450 a year for a research grant for Dr. Joseph Needham. Mentioning the bestowal of the Order of Merit upon Prof. E. D. Adrian, he said that this reflected the importance of work recently undertaken for the nation. In addition to 15 vacant Chairs there are now 16 Professors, together with 3 Readers, absent on national service, and out of 370 university lecturers and demonstrators only 143 remain in Cambridge. Several of the former holders of professorships have consented to remain in charge of their departments for the time being.

The Final M.B. Examination will begin in the present term on Monday, Dec. 7, a day earlier than is prescribed by Ordinance, the written examination for Part I being held that day and for Part II on Dec. 8 and 9. Names of candidates for the M.Chir. Examination should be sent to the Registrary by Dec. 29; the examination begins on Feb. 16.

UNIVERSITY OF SHEFFIELD

The following candidates have been approved at the examination indicated:

Final M.B., Ch.B.—*Parts II and III*: H. M. A. Ansari, Josephine Hall, J. D. H. Linfoot, E. R. Monypenny, Ethel M. Spedding, R. L. N. Stewart, Joan Williams.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a quarterly meeting of the Council, held on Oct. 8, with Sir Alfred Webb-Johnson, President, in the chair, it was decided to increase the membership of the Court of Examiners from 17 to 20. The Council decided to offer the use of the library as a meeting place for Canadian and American medical officers.

Mr. A. J. Graham was nominated as the fiftieth Jenks Scholar. A Leverhulme Scholarship was awarded to F. K. Sanders, M.A., D.Phil.Oxon, for a year from Sept. 30. Subject of research: Problems connected with the repair of peripheral nerve injuries. Dr. Douglas E. Lea was nominated for reappointment as a Prophit Student for 1943 and Dr. Lilian Helena Walter was nominated for appointment as a Prophit Student as from Aug. 18, both for cancer research. Dr. Geoffrey Bourne has been reappointed a Mackenzie Mackinnon Research Fellow for a second year from Oct. 1. A vote of thanks was accorded the trustees of the Powell-Cotton Museum for a generous donation of comparative osteological material given as a token of sympathy with the College in the disaster to the museum. The general annual report and the scientific report on the Museum and Research Laboratories were approved and copies will be sent to such Fellows and Members as apply for them.

Diplomas of Membership were granted to T. D. Kellock, H. G. McQuade, J. R. K. Preedy, D. S. Short, Edith M. Waterhouse, J. F. R. Withycombe.

Diplomas in Child Health were granted, jointly with the Royal College of Physicians of London, to the following candidates:

A. P. Bentall, E. Emanuel, E. G. Fox, J. F. Galpine, Aitolia Georgiadis, Margaret E. Harker, D. C. Jackson, Elizabeth B. S. Scobbie, Vera Settle.

Obituary

F. G. CHANDLER, M.D., F.R.C.P.

We regret to announce the death on Oct. 8 of Dr. F. G. Chandler, physician to St. Bartholomew's Hospital and senior physician to the London Chest Hospital, Victoria Park, E.

Frederick George Chandler was born at Sutton, Surrey, on July 25, 1885, and from the Leys School entered Jesus College, Cambridge, with a scholarship and gained first-class honours in the Natural Sciences Tripos of 1908. He went on to St. Bartholomew's Hospital, took the English Conjoint Diplomas in 1911, and the M.B. and B.Ch. degrees a year later. For his Cambridge M.D. thesis in 1917 he won the Raymond Horton-Smith prize. After holding a house-physiciancy at Bart's he was appointed medical registrar at the London Hospital in 1913, but was seconded from this post during the last war, when he served with a temporary commission in the R.A.M.C. as regimental medical officer to the 2nd Argyll and Sutherland Highlanders, and later as medical specialist at a casualty clearing station. On returning to civil practice in 1919 he took the M.R.C.P. and was elected to the visiting staff of the Victoria Park Hospital, where he did excellent work, and after two years as casualty physician at Bart's he became assistant physician and medical tutor at Charing Cross Hospital. He was elected F.R.C.P. in 1925. Chandler's promotion was rapid at Charing Cross, but about twelve years ago a vacancy occurred at St. Bartholomew's and he was elected assistant physician. He was also on the consulting staff of King Edward VII Sanatorium and of the Hospital for Tropical Diseases. His book, written jointly with Dr. W. Burton Wood, on *Lipiodol in the Diagnosis of Thoracic Disease*, appeared in 1928.

[*Press Portrait Bureau*

Chandler joined the British Medical Association in 1923 and was a member of the Consultants Board at headquarters for the past ten years. He held office as honorary secretary of the Section of Medicine when the Association met at Bath in 1925, as vice-president of the Section of Public Health (including tuberculosis) at Bournemouth in 1934, and as vice-president of the Section of Tuberculosis at Plymouth in 1938. He was an enthusiastic worker, with varied interests outside his profession, including music and botany.

Sir Percival H.-S. Hartley sends the following appreciation:

By the death of Dr. Frederick Chandler the profession of medicine loses one whom it can ill spare, for he was a man of high principles and wide culture, one who had already made his mark in his profession, and would have attained even higher eminence had he been spared. A classical scholar of Jesus

College, Cambridge, he afterwards entered St. Bartholomew's Hospital, becoming later my house-physician and proving one of the very best with whom it has been my privilege to work. There being no immediate vacancy in prospect at St. Bartholomew's he became medical registrar at the London Hospital, and then assistant physician at Charing Cross, but was later recalled to his "Alma Mater" and appointed assistant physician and later physician to St. Bartholomew's. Meanwhile he had made his reputation at the Victoria Park Hospital as a physician skilled in chest diseases, and was one of the pioneers in England of the delicate operation of dividing the pleural adhesions which prevent the full efficacy of an artificial pneumothorax, thus greatly increasing its value. For his eminence in chest work he was appointed—with the approval of H.M. the King—one of the consulting physicians of the King Edward VII Sanatorium, Midhurst. Here he did valuable work, rapidly endearing himself to his colleagues by his devotion to duty and charming personality. He was in middle life, and in the heyday of his success, when he suddenly, a few months ago, found himself smitten by a mortal disease. But with the utmost fortitude and Christian resignation he accepted the position and with cheerful courage continued to receive his friends, never once allowing himself a single word of complaint. He passed away peacefully at his home at Newdigate, Surrey. Of his happy family life, and the deep devotion and courage of his wife, who nursed him tenderly to the end, it is not for me to speak. But the hearts of all who knew him go out to her and their children in their sorrow and distress. Men like Dr. Chandler, followers of St. Luke in the highest and best sense, our profession can ill afford to lose, and it is with emotion and heartfelt sorrow that we say farewell.

ROBERT CECIL ROBERTSON, *M.C.*, M.D.

News has been received of the death in Hong Kong on August 4 of Robert Cecil Robertson, professor of pathology and bacteriology at Hong Kong University. Dr. Robertson was born in 1890 at Kilmarnock, and entered Glasgow University, graduating in medicine just before the outbreak of the last war. He served with the R.A.M.C. during that war and gained the Military Cross. Afterwards he resumed his medical studies, and in 1919 took the M.R.C.P.Ed. and the D.P.H., in 1920 the F.R.F.P.S., and a year later the M.D.Glasg., with commendations.

Robertson chose a career in the Far East, and for many years was a member of the staff of the Henry Lester Research Institute in Shanghai, serving as head of the Division of Pathology. He was also assistant pathologist to the Shanghai Health Department. His appointment to the chair at the University of Hong Kong was quite recent; he took up his work there only in 1940, and his brief tenure was thus an adventurous and troubled one owing to the spread of the war in the Far East and the occupation of the colony. He was exactly the type of man to represent Great Britain in that part of the world—a man of boundless physical and moral courage, a keen humanitarian, and a vigorous champion of the cause of the Chinese, among whom he had hosts of friends. He was robust in the expression of his views and strove zealously to improve the hygiene of the Chinese populations. He served as commissioner of the League of Nations anti-epidemic unit No. 2, which made health surveys in China, and in that capacity carried out some important missions. His epidemiological survey in 1939, when he tackled the difficulties of the Burma Road and presented a valuable report to the League Commission, is specially notable. He distinguished himself greatly in the rescue and rehabilitation work following the Yangtze floods in 1931. In August, 1937, when the Chinese attacked the Japanese flagship at Shanghai and bombs fell disastrously in the International Settlement, Robertson was officially reported among the 2,000 dead, but the anxiety of his relatives in this country was presently relieved by a laconic cablegram from him bearing the single word "unharmed." He contributed occasional papers to the specialist medical journals, in particular studies on the bacteriology and treatment of fevers in Shanghai. Unfortunately, his acceptance of the position in Hong Kong, where in other circumstances he might have done a very great work, was followed almost immediately by a breakdown in health, and in 1940, owing to continued illness, he ceased to belong to the Reserve of Officers. He was a member of the B.M.A. from 1917 until 1942.

In the off times of a very active career Robertson turned to the painting of pictures, in which his wife, a Scottish lady, also excelled. A picture of his painted in Shanghai was hung in the Royal Academy in 1937. He was also an accomplished photographer and an ardent scientist in many directions apart from those which constituted his lifework.

JOHN WALTER CARR, C.B.E., M.D., F.R.C.P., F.R.C.S.

Dr. J. Walter Carr, for many years a well-known physician in London, died on Sept. 29 at Hampstead. He was a Londoner by birth and education, and in London he spent the whole of his professional career. He entered University College and Hospital for his medical training, qualifying in 1884, and taking his M.B., B.S.Lond. with first-class honours in medicine, obstetric medicine, and surgery. In 1887 he proceeded M.D., and became a Fellow of the Royal College of Surgeons in the same year. His principal hospital association was with the Royal Free, where he was for many years physician, and, after his retirement from the active staff, consulting physician. He was also lecturer in medicine to the London School of Medicine for Women, which is associated with that hospital. Another institution he served with great devotion was the Victoria Hospital for Children at Chelsea.

Dr. Carr, who became Fellow of the Royal College of Physicians of London in 1901, served the college in many capacities—as a member of its council, an examiner, and, in 1926-7, as censor—and he attended Comitias up to the present year. He was also examiner in medicine to the University of Birmingham and the Society of Apothecaries. For a number of years he was a prominent member of the Medical Society of London, and in 1928 was elected its president. He had also been president of the Clinical Section of the Royal Society of Medicine. In all these capacities and others he gained the esteem and regard of his professional colleagues to an unusual extent. Forty years ago he published, jointly with three colleagues (T. Pickering Pick, Alban Doran, and A. Duncan), *The Practitioner's Guide*, and in 1916, when he himself was in the middle fifties, he wrote a book entitled *How to Live Long*, and verified its precepts by living for another quarter of a century; he was in his eighty-first year. Apart from these, he wrote numerous papers on medical subjects, particularly articles in various textbooks on tuberculosis and diseases of the pleura and mediastinum.

In 1920 he was made Commander of the Order of the British Empire, and in 1929 he had the unusual honour for a medical man of being elected Master of the Haberdashers Company, which stands high in precedence among the great City guilds. Dr. Carr retired from active practice several years ago, but he continued to live in London, and followed his favourite recreations—walking and travelling. His wife died in 1937, and he is survived by a son and three daughters.

The Services

The D.S.C. has been awarded to Temp. Surg. Lieut. G. MacBain, R.N.V.R., for courage and devotion to duty in North Russian waters, and to Temp. Surg. Lieut. A. W. Clark, R.C.N.V.R., for bravery, endurance, and devotion to duty in action against the enemy in the Mediterranean.

Temp. Surg. Lieuts. D. R. Barry and S. G. Hamilton, R.N.V.R., have been mentioned in dispatches for bravery, endurance, and devotion to duty in action against the enemy in the Mediterranean and for great bravery and devotion to duty when H.M.S. *Prince of Wales* and H.M.S. *Repulse* were sunk by Japanese aircraft respectively.

CASUALTIES IN THE MEDICAL SERVICES

Acting Lieut.-Col. Cornelius McGrath, R.A.M.C., who is included as "died" in an Army Council Casualty List published on Oct. 1, graduated M.B., B.Ch., B.A.O. of the National University of Ireland in 1936. He immediately entered the R.A.M.C., was promoted capt. a year later, and recently became major.

Major James Grant Morrin, R.A.M.C., is included as "died" in an Army Council Casualty List published on Oct. 1. Educated at St. Mungo and Anderson Colleges, Glasgow, he took the Scottish triple qualification in 1912, and served in the R.A.M.C. in France in the war of 1914-18, attaining the rank of capt. After demobilization he settled in practice in Lambeth in 1922 and represented his constituency at the Annual Representative Meetings of the B.M.A. at Belfast in 1937 and Plymouth in 1938 and was honorary secretary of the Lambeth and Southwark Division in 1938-9. On the outbreak of the present war he was immediately recalled for service.

Major Douglas James Stirling Armstrong, R.A.M.C., has died on active service in Malta. He was educated at the University of Glasgow, where he took the degrees of B.Sc., M.B., Ch.B. in 1938, and the D.P.H. in 1940. He was a member of the B.M.A. A. G. H. writes: When the full story of the epic defence of Malta comes to be told, the name of Dr. Armstrong will be found to occupy a prominent place. Joining the R.A.M.C. as a volunteer shortly after the outset of war, he was appointed in January, 1941, as commanding officer, 57th Field Hygiene Unit. He thus became, at the age of 25, sole consultant and adviser in hygiene to the military garrison of Malta. Up till the time of his death there were considerable periods when, by enemy action, light, ventilation, water, and sanitary facilities in great portions of the command were completely abolished. Despite these tremendous difficulties, the hygiene of the garrison remained at the highest possible level. These are bare facts. The decorations and well-earned honours would, no doubt, have followed. The present writer had the privilege of knowing Armstrong during the winter of 1941 and in the unforgettable spring of 1942 in Malta. Then, under the most ferocious aerial bombardment of a single small target, Major Armstrong in his equanimity and perseverance showed all those characteristics of courage and endurance which have distinguished great Scotsmen. When his headquarters were hit for the third time and almost completely destroyed, he remained unperturbed and set about the heavy work of reorganization swiftly and efficiently. To everything he did during these hectic eighteen months he added a touch of distinction and individuality entirely his own, whether in painting those water-colours of post-mortem lung-blast appearances which we in his profession will later admire, or whether investigating epidemic jaundice.

Surg. Lieut. Robert Davies Royds, R.N.V.R., who has died in a hospital in Algeria, was born on July 8, 1914, the elder son of Mr. and Mrs. R. Royds, and was educated at the Grove Academy, Broughty Ferry, and at St. Andrews University, graduating M.B., Ch.B. in 1937. Appointed a Carnegie research scholar, he worked under Prof. D. F. Cappell at University College, Dundee. He entered the R.N.V.R. in July, 1940, and had been interned in Algeria since his ship, H.M.S. *Havock*, ran aground.

Wounded.—Major M. E. M. Herford, M.B.E., R.A.M.C.

Wounded and Prisoner of War.—War Subs. Capt. R. J. F. Howe, R.A.M.C.

Prisoners of War.—Capt. W. Falconer, R A M.C., Capt. F. E Gallash, A.A.M.C., Lieut -Col. L. E. Le Souef, A.A.M C., Lieut.-Col. J. T. Lewis, R.A.M.C., Capt. M. Mayrhofer, A.A.M.C., Major J. D. Palandri, A.A.M.C., Surg. Lieut. E. C. Powell, R.N.V.R., Major J. W. Redgate, R.A.M.C.

Missing.—Capt. A. E. Brewer, R.A.M.C, Capt. B. A. Hunt, A.A.M.C., Major B. W. Nairn, A.A.M.C.

DEATHS IN THE SERVICES

Major-General Sir Samuel Guise Guise-Moores, K.C.B., K.C.V.O., C.M.G., late R.A.M.C. (ret.), died at Cheltenham on Oct. 3, aged 78. He was born at Deesa in Gujarat on Dec. 24, 1863, the son of Col. S. Guise-Moores of the Devon Regiment, and was educated at Cheltenham College and at St. Thomas's and King's College Hospitals, taking the M.R.C.S., L.R.C.P. in 1888, and the D.P.H. in 1898. After filling the post of house-surgeon to the East Devon and Cornwall Hospital at Plymouth, he entered the Army as surg. in 1890, became col. in 1915, major-general in 1920, and retired in 1923. He had a long and very distinguished career. His first war service was in the Chitral campaign of 1895, with the relief forces (medal and clasp). He also served in the South African War, in the relief of Kimberley, and in the actions of Belmont, Enslin, Modder River (wounded), and Magersfontein, and later in the actions of Poplar Grove, Vet River, Pretoria, and Diamond Hill (twice mentioned in dispatches, Queen's medal with 6 clasps and King's medal with 2 clasps). In the war of 1914-18 he served throughout in France and Flanders in administrative posts and was A.D.M.S. of several successive divisions at Ypres, on the Somme, and at Passchendaele. In 1917 he became D.D.M.S of the 11th Corps and later D.M.S. of the 2nd Army and of the Army of the Rhine (mentioned in dispatches five times). In 1919-20, he served as commandant of the R.A.M. College, and after retirement was appointed house governor and medical superintendent of the Osborne Convalescent Home for Officers, relinquishing the post in 1931. From 1927-33 he was a colonel-commandant of the R.A.M.C. Among many other activities he was principal medical officer of the National Rifle Association from 1908 to 1914 and was in medical charge of the Wembley Exhibition. Early in the century he served for some years as surgeon major in the Scots Guards. He was granted many well-deserved honours: C.B. in 1915; C.M.G. in 1918; K.C.B. in 1925; K.C.V.O. in 1931; Honorary Surgeon to the King in 1923. He also held the French Croix de Guerre and the Belgian Order of King Leopold. He was president of the Southern Branch of the B.M.A. in 1929-31 and chairman of the Isle of Wight Division in 1928-31.

Major-General Charles Harford Bowle-Evans, C.M.G., C.B.E., M.C., I.M.S. (ret.), died at Cheltenham on Aug. 23, aged 74. He was born at Tewkesbury on Oct. 19, 1867, the son of Lieut. John Bowle-Evans, Rifle Brigade (ret.), and was educated at the University of Cambridge, where he graduated B.A. in 1889 and M.B., B.Chir. in 1894, subsequently taking the D.P.H. in 1910, and at St. Bartholomew's Hospital. He entered the I.M.S. as surg. lieut. in 1894, became col. in 1920, major-gen. in Sept., 1923, and retired in the following Dec. He was appointed Director-General of Medical Services in India in 1923 in succession to Sir C. H. Burtchall, but only held the post for two months, having to retire on account of ill-health. He was the first I.M.S. officer to hold that post, except that the late Sir C. P. Lukis held it for a few months during the war of 1914-18. He received the C.M.G. in 1915, the C.B.E. in 1920, and in 1923 was appointed Honorary Physician to the King. He had a long list of war service: North-West Frontier of India, Waziristan, 1894-5 (medal with clasp); Chitral, 1895, action of Malakand Pass, relief of Chitral (medal with clasp); China, 1900 (medal); and the war of 1914-21, when he was twice mentioned in dispatches and gained the M.C.

Medical Notes in Parliament

Mass Radiography

Mr. James Griffiths asked Mr. Brown on Oct. 8 for a statement on tuberculosis. Mr. Brown replied that the committee which was appointed by the Medical Research Council at his request had completed its report, which was published that day. He had taken action on a number of points included in the recommendations. To facilitate early diagnosis the Ministry of Health obtained priority for the supply of some 30 sets of equipment for mass radiography. It was allocating them to large centres of population where they could be used to the best advantage, and in consultation with local authorities and with the assistance of an expert committee it had arranged for the training of the necessary staff to operate this equipment Deliveries of the equipment would be gradual. Arrangements for operation in the individual districts and for co-operation between authorities had to be worked out in detail. He expected that an effective start will be made in the New Year. Additional beds were being allocated and action was being taken to meet the needs for nursing and domestic staff. Where facilities for diagnosis and treatment were available it was important that those who give up work temporarily for treatment should be able to do so without anxiety as to the maintenance of their dependants. Local authorities were accordingly being authorized to grant financial assistance in such cases for the maintenance of dependants and to avoid breaking up the home while the breadwinner underwent treatment. This assistance would be administered by the public health authorities as a part of the approved treatment under the tuberculosis scheme. The cost would be repaid from Exchequer funds. Mr. Johnston was making similar arrangements in Scotland.

Dr. Summerskill asked what Mr. Brown was doing to reduce the incidence of non-pulmonary tuberculosis, which could be traced to milk. Mr. Brown said the Ministry of Health was in touch with the other Ministries concerned in that matter. Captain Elliston asked whether the mass radiography sets would be available for selected counties and county boroughs where the medical officer of health had submitted an approved scheme. Mr. Brown said the Ministry would work in co-operation with the local authorities. Sets were transportable but were best kept at places where they could be used for a period. The work would be done in connexion with the arrangements at local sanatoria. Men discharged from the Army who were tuberculous would come under the general arrangements of the scheme. Sir Francis Fremantle asked whether Mr. Brown would consult the Ministries of the Fighting Services so that these would use the sets to prevent tuberculous men getting into the Services. Mr. Brown replied that the Services had taken the initiative in the use of mass radiography.

Duodenal Ulcers in Invalided Men

Sir Irving Albery asked the Secretary of State for War on Oct. 13 how many men had been invalided out of the Service suffering from duodenal ulcers, and if any inquiry had been made about the cause. Sir James Grigg said that it was not in the public interest to give the precise figures, but the proportion of men invalided from the Army suffering from duodenal ulcers was about 11% of the number invalided on account of all diseases. There was no evidence to show that Army life rendered men more liable to duodenal ulcers than they would be in civil life, and he was satisfied that no special inquiry was necessary.

Yellow Fever.—On Oct 13 Sir James Grigg said that three cases of yellow fever had been diagnosed in British troops in areas in which they had been stationed since the commencement of the present war. Vaccination against yellow-fever of British troops proceeding to yellow fever endemic areas was introduced before the war, and had been continued without interruption. Most of the vaccine used was manufactured in this country, but some supplies were obtained from the U.S.A.

Routine Tuberculin Test for Children.—Sir E Graham Little, on Oct 13, asked the Minister of Health whether, in view of the rise in the incidence of tuberculosis, especially in children under 5, and of the present impracticability of wider use of radiography in detecting tuberculosis, he would impress on medical officers under his jurisdiction the diagnostic value, especially in the case of infants and young children, of properly performed tuberculin tests. Mr Brown replied that the report of the committee of the Medical Research Council on Tuberculosis in Wartime stressed the importance of the routine use, in all tuberculosis dispensaries, of the tuberculin test in children particularly The report was being brought to the notice of all medical officers of health of tuberculosis authorities.

Notes in Brief

It has been decided to appoint a woman naval surgeon at one of the W.R.N.S. establishments Other appointments are under consideration.

The sensitivity of certain persons to national flour is at present under consideration by the Food Rationing (Special Diets) Advisory Committee of the Medical Research Council.

Supplies of quinine are adequate for a considerable period.

Medical News

The Duke of Gloucester has accepted the post of President of King Edward's Hospital Fund for London, in succession to the late Duke of Kent. He is the sixth member of the Royal Family to hold the presidency. Since its foundation in 1897 by King Edward VII, when Prince of Wales, the fund has distributed £10,500,000.

The Section of Comparative Medicine of the Royal Society of Medicine opened its 1942-3 session on Oct. 21. Further meetings have been arranged for Dec. 16, Feb. 17, and April 14, and, like the first, will be devoted to aspects of immunity.

The Royal College of Nursing (Henrietta Place, Cavendish Square, W.1) has arranged a dietetic course for nurses In planning the course the College has had help from the Ministry of Food and from members of the British Postgraduate Medical School staff, many of whom will give lectures to the students. Practical experience will include six months in the Hammersmith Hospital dietetic department, a month in the main kitchen and stores department of the London Hospital, and short periods in dietetic departments and clinics of other London hospitals.

Concentrated orange juice is to be distributed to children at welfare centres and food offices in place of the blackcurrant juice of last winter. It is prepared according to specifications of the Ministry of Food by pharmaceutical firms possessing the necessary plant, from concentrated orange juice imported from America. Special precautions are taken to prevent contamination and to ensure a minimum loss of vitamin C. The label states that the vitamin C content is 60 mg. ascorbic acid per fluid ounce, or about 160 mg. per 100 grammes. The juice should be kept in a cool dark place The Ministry of Food states that small air bubbles in the neck of the bottles are due to shaking during transport and not to fermentation.

The Board of Education has issued a leaflet, "War-time Diet in Boarding Schools," being Memorandum No. 34 of the series on the Schools in War-time There is a foreword by Sir Wilson Jameson Copies (price 2d.) can be obtained through any bookseller or direct from H.M Stationery Office.

Dr. John Young of Wimbledon Common, London, formerly of Blackpool and of Glasgow, among a number of legacies to hospitals and other charities, bequeathed £1,000 and a share of his residuary estate to the Royal Medical Benevolent Fund. Mr. H B. Grimsdale, F.R.C.S., bequeathed, subject to his wife's life interest, £500 each to the R.M.B.F., the Westminster Ophthalmic Hospital, and the Royal College for the Blind, Norwood.

No. 39

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Oct. 3.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for. (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for (a) The 126 great towns in England and Wales (including London). (b) London (administrative county) (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1942					1941 (Corresponding Week)

Stillbirths	201	32	27			187	14	49		
Rate per 1,000 total births (including stillborn)			31					52		

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes paratyphoid A and B for Northern Ireland.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

n *England and Wales* the outstanding features of the returns were the large rise in the notifications of scarlet fever and measles—460 and 445 respectively in excess of last week's totals—and the continued prevalence of dysentery, which was only 5 below last week's record level. There was a rise in the ncidence of diphtheria, 53 cases, and acute pneumonia, 49, while there were 93 fewer notifications of whooping-cough than in the preceding week.

The returns for scarlet fever showed small rises for most areas, although the increase was most pronounced in the North: Yorks West Riding 128, Lancashire 49, Staffordshire 35.

The only noteworthy local increase in the incidence of diphtheria was in Durham, where 33 cases in excess of last week's total were recorded. Diphtheria is more prevalent in the northern section of the country than in the southern, and the three counties of Lancashire 140, Yorks West Riding 104, and Durham 97 cases account for 40% of the total for the country.

The rise in the incidence of measles was fairly general throughout the country, the only large increases being in Yorks West Riding 169, and Cheshire 121 cases. Of the 791 cases notified in the former county 224 were in Leeds C.B., and of the 296 cases in the latter county 71 were in Bebington M.B. The most notable exceptions to the increasing trend were those of London and Warwickshire with 48 and 27 fewer cases than in the previous week.

In *Scotland* there were further increases in the incidence of scarlet fever and measles. The weekly notifications of scarlet fever have risen from 275 to 455 during the past four weeks; the largest totals during the present week were for Glasgow 102, and for Edinburgh 77. Notifications of measles have steadily risen during the past five weeks from 72 to 185, the principal centres of infection being Dundee and Paisley Burgh, with 49 and 48 cases respectively.

In *Eire* the relatively high incidence of poliomyelitis was maintained, 8 of the 21 cases being notified in Dublin. An outbreak of typhoid in the rural district of Dingle, Co. Kerry, accounted for 14 of the 17 cases notified.

Dysentery

The high incidence of dysentery recorded last week in England and Wales was repeated again during the week. The largest of the new outbreaks was 19 cases in Hertfordshire. Elstree R.D. An increase occurred in the two centres of infection in Wales: in Caernarvon, Conway M.B., the number of cases rose from 5 to 13, and in Glamorganshire, Cardiff C.B., from 6 to 30. In Southampton there was an increase of from 15 to 21 (Basingstoke R.D. 8, Droxford R.D. 13). The number of cases in Yorks North Riding, 25, was the same as in the preceding week (Middlesbrough C.B. 25). The outbreak in this town has caused 9 deaths; 8 of them were in children under 4 and the other in a person of 50. The cause of the outbreak has not been determined; bacteriological examination of milk, water, and ice-cream yielded negative results. In Essex the total declined from 39 to 33; no further cases were reported in Chelmsford R.D., where 27 cases were notified last week; this week's cases were in Colchester M.B. 17, and in Hornchurch U.D. 16. The incidence in Norfolk declined from 40 to 13 (Norwich C.B. 12); the large outbreak in the preceding week, 30 cases in Swaffham R.D., produced only one further case.

Other county totals of note during the week were London 19. Middlesex 11, Surrey 10; these were distributed among several administrative areas within the county.

Small-pox

According to a Press statement on Oct. 17, 10 more cases of small-pox have appeared in Methilhill, Fife, bringing the total up to 21. The County M.O.H. is reported as having said that there is a possible connexion between the Methilhill and the Glasgow outbreaks.

Returns for the Week Ending October 10

The notifications of infectious diseases in England and Wales during the week included the following: scarlet fever 2,613, whooping-cough 972, diphtheria 991, measles 4,650, pneumonia 541, cerebrospinal fever 57, acute poliomyelitis 23, dysentery 209, paratyphoid 11, typhoid 6.

The Minister of Health, at the opening of a wartime nursery at Hull, said that during the present month the thousandth nursery for women war workers' children would come into operation. At the end of September there were 937 nurseries opened in England and Wales, caring for 40,000 children under 5 years of age.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A House, Tavistock Square, London, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

Telephone No.—B.M.A. and *B.M.J.*: EUSTON 2111.

Telegraphic Addresses.—EDITOR, *Aitiology Westcent, London;* SECRETARY, *Medisecra Westcent, London.*

B.M.A. Scottish Office: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Glasses after Operation for Cataract

"Cataract" writes: Will any sufferer who has had his lenses successfully removed inform me if bifocal glasses are satisfactory, and if cemented segments are necessary, or can the bifocals be cut out in one piece? If so, can this be done with Percival lenses? I have slight astigmatism.

Any Old Bones?

"Enquirer" would be grateful to learn where a medical student can obtain a set of bones or a half skeleton.

Death by Lightning

Dr. H. M. Stanley Turner writes: In 1936 a paper entitled "Electrical Traces" was read before the Royal Society of Edinburgh by Prof. Jellynek, who occupied the chair of electropathology in Vienna University. It was illustrated by films, and the author claimed that high-potential electrical discharges through the living tissues of plants and animals left what he termed "electrical traces" in the tissues concerned. He stated that these took the form of curves or spirals which could be easily identified in sections under the microscope, and illustrated his claims by slides of photomicrographs upon the screen. If Prof. Jellynek's claims are confirmed such findings would be of potential importance to medical jurists, and it would be interesting to know whether there has been confirmation from other sources. This inquiry is prompted by "Notes on a Case of Death by Lightning" in Medical Memoranda in your issue of Oct. 10, 1942.

Aspirin for Asthma

Dr. Alexander Francis (London, W.1) writes: It has long been known that aspirin relieves asthma in many cases, but now that so much prominence has been given to the fact by the letters of A. K. (Sept. 19, p. 356) and others, it is well to repeat the warning which I first sounded in the *British Medical Journal* (Aug. 16, 1919)—that there is great danger in giving aspirin to a patient with nasal polypi. If a patient with a history of nasal polypi has a high blood pressure the risk is not great, but in low blood pressure cases most alarming symptoms are likely to be instantly produced, which is further evidence, if such were needed, of the vasomotor origin of asthma.

Dr. W. Lees Templeton (Highgate, N.6) writes: It is an extraordinary fact that whenever the logical explanation of the action of a drug in any condition is that it is homoeopathic the orthodox practitioner will go out of his way to suggest that it is faith or hope, but never charity—to wit, homoeopathy! Aspirin in some people will produce asthma. Asthma in some people will be relieved by small doses of aspirin! Need one go further?

Income Tax

Two Separate Appointments—Expenses

"Y. Z." holds an appointment as assistant radiologist at one hospital and another appointment as visiting radiologist at the municipal hospitals. Salaries are paid separately; no private practice is allowed. The inspector of taxes states that as the two appointments are assessable separately no travelling expenses are allowable.

⁂ Assuming that "Y. Z." cannot show that the holding of one appointment is a condition attaching to the other the inspector is legally correct, though the result is rather unfair on our correspondent. If, however, there are two or more municipal hospitals, "Y. Z." can claim such part of his car expenses as fairly represents the amount spent on travelling between them.

Travelling Expenses—Use of Car

"Q. Q." is attached to an R.A.F. camp as a medical specialist. Mess accommodation is limited and he lives four miles away from the camp. He has to be available for emergencies. Can he deduct the cost of maintaining a car—including the depreciation for travelling to and from the camp?

⁂ The legal rule is strict—the expense of travelling between the place of residence and the place of work is not regarded as incurred "in the performance of the duties"—and we are not aware of any concession covering the facts. It might, however, be worth while writing to "The Chief Inspector of Taxes, the Hydro, Llandudno, N. Wales," explaining the circumstances and inquiring whether some concession cannot be made to meet the equity of the case for an allowance.

Change in Nature of Appointment

"M.R.C.S." was employed as a house-surgeon from Nov. 28, 1940, to March 31, 1942. He began work as assistant tuberculosis officer at £724 per annum, less 6% for superannuation as from April 20, 1942. On what amount should he be assessed for 1942-3?

⁂ He is not entitled to be assessed on the basis of the previous year; the difference in the work and the terms of remuneration are such as to constitute his present appointment a new source of income. On the facts stated his liability for 1942-3 is as follows:

	£	s	d	£	s	d.
Gross earnings April 20, 1942, to April 5, 1943—i e., 350/365ths of £724	693	0	0			
Less superannuation deduction	41	0	0			
Amount of gross assessment				652	0	0
Allowance for married man	140	0	0			
Allowance for earned income (1/10th of £652) .	65	0	0			
				205	0	0
Amount of net assessment				£447	0	0
	£	s	d			
Tax on £165 at 6s. 6d in the £	53	12	6			
Tax on £282 at 10s in the £ . . .	141	0	0			
				194	12	6

(Of this amount £32 should ultimately be received by "M R C S." in the form of a post-war credit.)

Repayment Claim—Agent's Commission

"Beta's" accountant has charged him £25 (i e., 10%) for his services in obtaining repayment of £257. Is this the usual practice?

⁂ Professional accountants base their charges not on a percentage of the amount repaid but on the time spent on the case and on its degree of difficulty. Repayment agents frequently adopt the percentage basis, and 10% is not uncommon. Whether, in fact, £25 was a reasonable charge really depends on just what the agent had to do by way of preparing special statements, collecting evidence of what tax had been suffered, and so on.

LETTERS, NOTES, ETC.

Home Drying of Fruit and Vegetables

Mr. B. G McLellan, F.I.C, has produced a practical leaflet on "Home Drying of Fruit and Vegetables," which should be of interest to medical men who possess gardens or orchards and wish to preserve surplus vegetables or fruit for winter use We understand that the author (Beverley House, Clifton, York) is willing to send copies to doctors on receipt of a stamped and addressed envelope

Bleeding Tooth Sockets

Mr. Joseph Angelman (Colchester) writes: I have read with interest the letters dealing with the arrest of dental haemorrhage sent by Dr. Le Fanu (Aug 15, p. 208), Dr. J. T. Maclachlan (Sept. 19, p. 356), and Dr. S. Jung (Oct. 10, p 444). I have never been able to understand why the doctor, when dealing with oral and dental tissues, should forget the elementary principles of surgery. Would Dr. Jung plug a bleeding cavity elsewhere in the body with a cork? I think not. Similarly, I am sure Dr. Le Fanu would be very chary about using the silver nitrate stick to arrest haemorrhage from cavities other than in the mouth. The treatment of dental haemorrhage demands the arrest of bleeding without injury to the surrounding soft tissues. Silver nitrate is a very powerful escharotic and when in contact with the oral tissues rapidly destroys them. As a dental surgeon may I suggest the following procedures. Examine the bleeding area; if there is a gentle oozing and remains of a blood clot, remove the latter and wash out the socket with warm water. Place a small pad of gauze, which may be impregnated with some styptic such as tannic acid, over the socket; over this place larger pieces of gauze or lint, and instruct the patient to bite reasonably hard, and to maintain pressure for a minimum of five minutes. It is the pressure which is important. In many cases this will suffice If there is a more persistent flow from the socket, especially from one point, it indicates a partially ruptured arteriole in the mucoperiosteum surrounding the socket. Suturing is the ideal method of treatment. Place a suture through the buccal and lingual (palatal, as the case may be) mucoperiosteum, and draw the tissue against the bony walls of the socket, thus compressing the bleeding-point. Tie the suture over the socket opening In the vast majority of cases this will immediately arrest the haemorrhage. When dealing with the true bleeder type where the persistent haemorrhage is due to some systemic or haematogenous factor, the local treatment should be supplemented with intramuscular haemoplastin, which is very successful. In very severe cases continued pressure by closure of jaws with a bandage may have to be used. The treatment of the haemophiliac patient does not come within the scope of this letter.

Conjoined Twins

Dr. James A. Rooth (Brighton) writes: I was much interested in the report of a case of conjoined twins by Dr. E. Ridehalgh (July 4 p. 10). In 1909 I had a case of this sort, but the course it took was very different. The twins were joined back to back and the point of union was the coccyx; the union was thought to be cartilaginous, but the movement was very restricted, though evidently much more than in the case you report. The labour however, was practically uncomplicated and lasted about 16 hours the mother being a young primipara of 21. The first twin was born by a vertex presentation in the first position after a slight delay which revealed the true state of affairs; the second was delivered in a similar manner. The process was evidently one of evolution of the second or podalic child, and this seems to have been the method of birth in the few similar cases recorded; in each case the second child underwent evolution owing to traction of the ligament. It will be seen that there was no undue delay, no anaesthetic, and no laceration of the mother, which was remarkable seeing that the twins weighed 13 lb. together The chief points of difference between the two cases are that there was freer movement in my case, and that the twins lived and are still alive in America, and have, I believe, made a good living on the variety stage.

MEDICINE 100 YEARS AGO

Extract from a clinical lecture delivered at the Westminster Hospital by Mr. G. J. Guthrie, printed in the *Provincial Medical Journal*, October 22, 1842:

"It appears that some gentlemen wish to run down this hospital, both as relates to the relief the poor receive, and the instruction which students may obtain at it, by inveighing strongly against the management which does and does not take place within its walls. I regret very much that many of the assertions of mismanagement are, in all probability, true as relates to the medical arrangements, several of which are not, in my opinion, fitting for a public hospital in London They are all of them, however, good, and well adapted for a parish infirmary; and as long as it may be thought right to continue them, the hospital must remain in a depreciated state, both as a place of refuge for the sick poor, and as a school of instruction When things become so bad that any change must be for the better, we may hope for improvement, and I care not how soon this takes place, for I confess I shall look forward with the hope that this hospital will then rise from its remains, and assume that character, and obtain that reputation, it never can have under existing circumstances. I have done my endeavour to remove the abuses and grievances of which I am sensible; but I abhor all disputes and squabbling, more particularly when they become personal, and I have no wish to contend with gentlemen whom I personally respect, although I believe them to be in error; and even if I thought it right to do so, I have not the time to spare which the forms of the hospital require.

"With respect to you as students, I have not recommended one to come here; I have not invited you in any way. You came because it suited your own views, and, being here, I am at all times happy to give you every information in my power. My days of attendance are Tuesdays and Saturdays, according to the rules of the hospital; but you will see a notice in the hall that I also attend on Thursdays, believing that every physician and surgeon should see every particular case three days a week, and when I have anyone in danger I visit him every day. You need never expect me before a quarter past one, and never wait for me after a quarter past two, before which time the assistant-surgeon will go round with you if I should be absent; and whenever he does the duty of one of the surgeons, he ought to receive a regulated proportion of the money which the seniors derive from the fees which you pay for permission to attend. I am never so contented as when you make yourselves constantly known to me, by obeying my injunctions, so frequently repeated, of walking up to me and repeating your names in my face."

NUTRITIONAL IRON DEFICIENCY ANAEMIA IN WARTIME*

PART I

THE HAEMOGLOBIN LEVELS OF 831 INFANTS AND CHILDREN

BY

L. S. P. DAVIDSON, B.A., M.D., F.R.C.P.Ed.&Lond. G. M. M. DONALDSON, M.B., Ch.B.
M. J. DYAR, M.B., Ch.B. S. T. LINDSAY, B.Sc., Ph.D.
J. G. McSORLEY, M.B., Ch.B.

(From the Department of Medicine, University of Edinburgh)

As we enter the fourth year of the war, with its consequent increased mental and physical strain and inevitable dietary restrictions, the assessment of the health of the nation becomes an urgent necessity. Nutritional deficiencies in a population can be assessed in various ways, the estimation of iron deficiency being one method. The advantage of this method is that iron deficiency can be accurately determined by estimation of haemoglobin concentrations. If such an investigation is made on representative samples of the population in wartime the results can then be compared with similar figures obtained in peacetime, and in this way the effect of war conditions on national health can be demonstrated.

Such an investigation is at present being carried out in Edinburgh on infants, school children, and women of child-bearing age, both pregnant and non-pregnant. The survey covers a representative cross-section of Edinburgh working-class population within these groups. This paper deals only with infants and school children; a second communication will be devoted to the haemoglobin levels in women.

An unselected series of infants and pre-school children from birth to 4 years of age have been examined at the infant clinic attached to the maternity pavilion of the Edinburgh Royal Infirmary, at district welfare clinics, and at wartime nurseries in Edinburgh. The group of school children comprised all the scholars between the ages of 5 and 12 years attending two primary schools which serve working-class districts of Edinburgh. The Haldane haemoglobinometer (13.8 g./100 c.cm. equalling 100%) was employed throughout the investigation. All apparatus used was checked against a standard set.

Infants and Pre-school Children (Birth to 4 Years)

This group comprised 442 individuals: 318 from birth to 23 months, and 124 from 2 to 4 years. None of them had received any iron therapy. A few children between the ages of 9 months and 4 years had been given 25 mg. of vitamin C daily. The results obtained are set out in Tables I and II, and in the accompanying Graph. Of the total number, 142 were examined at "wartime nurseries" which have been set up by the public health authorities to care for children whose mothers are undertaking whole- or part-time war work. Most of these children were supplied with a midday meal in the "nursery."

TABLE I.—*442 Infants and Pre-school Children (Birth to 4 Years) Average Haemoglobin Levels according to Age*

Age ..	< 1 m.	1 m.	2 m.	3 m.	4 m.	5 m.	6 m.	7 m.	8 m.	9 m.	10 m.	11 m.	12–17 m.	18–25 m.	2 years	3 years	4 years
No. of cases	18	37	42	28	19	15	14	12	13	8	18	11	48	35	29	43	52

4 yrs.	10	77·5	42	79·5	52	76·8
Totals ..	94		142		236	

The haemoglobin levels in the two groups in Table II are very similar, except in the age period 12 to 17 months, when the average haemoglobin level of infants examined at welfare clinics is notably higher than those seen at the wartime nurseries. The significance of this is referred to later.

School Children (5 to 12 Years)

This series consisted of 389 children attending two primary day schools in Edinburgh. The results are set forth in Table III in the form of haemoglobin levels at successive ages, and in Table IV as the percentage of children falling into successive haemoglobin ranges. It will be noted that the average haemoglobin level for the whole series, irrespective of age, is 80.3% (Table III), and 53% of the children have less than 80% of haemoglobin (Table IV).

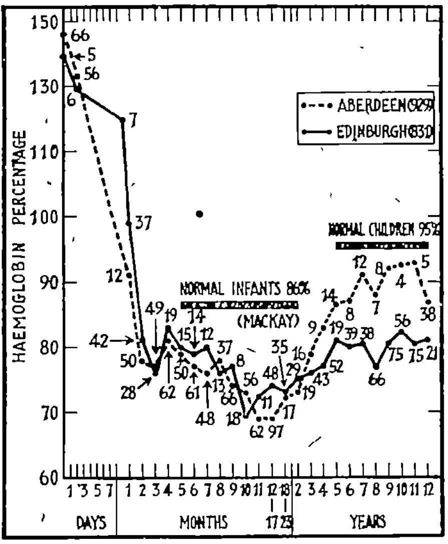
Discussion

Infants (Birth to 23 Months)

A curve has been constructed from the Edinburgh figures in Table I, and is shown in the graph. On the same graph is drawn the curve which was obtained by Davidson *et al.* (1935) in Aberdeen for children of the same age groups.



Graph showing haemoglobin percentages in the present series compared with those of a similar series investigated in Aberdeen in 1935.

The two curves show a close parallelism from birth up to 10 months, with a slightly higher level throughout in the Edinburgh series. From 4 months onwards there is a gradual fall in haemoglobin levels. This fall becomes more acute in both series from the eighth to the eleventh month. There follows a gradual rise until 2 years of age, which is more rapid in the Edinburgh series. The Edinburgh series therefore shows a slight improvement over the Aberdeen series which may or may not be significant. In addition, after the maximum fall in haemoglobin which occurs between the tenth and eleventh months, an earlier and more marked rise takes place in the Edinburgh group. This improvement could be attributed to the better milk supply for infants due to wartime regulations, or to better attendance at infant welfare clinics for expert advice during the critical period of weaning and the inception of a mixed diet. Although it may be some consolation to know that after three years of war no deterioration in haemoglobin levels of infants has been demonstrated, it should not be forgotten that anaemia in infants is still extremely common

Table V shows the percentage of infants at different haemoglobin levels (2 to 23 months) in the present Edinburgh series, and the comparable figures for Aberdeen and Edinburgh for the age groups 9 to 23 months. This table indicates that the incidence of severe anaemia (less than 61% haemoglobin) in infants of 9 to 23 months in the 1935 Aberdeen series is three times as great as in the 1942 Edinburgh series, but the percentage of moderately anaemic infants (61% to 70% haemoglobin) has risen by 10% in Edinburgh as compared with the Aberdeen figure. It will be noted that 83% of the Edinburgh infants and 87% of the Aberdeen infants between 9 and 23 months have a haemoglobin level of less than 80%.

Table V.—*Grades of Anaemia in Infants (2 to 23 Months); Edinburgh, 1942, and Aberdeen, 1935*

Place	Age	No. of Cases	Percentage of Children in Different Haemoglobin Ranges			
			Hb < 61%	Hb 61–70%	Hb 71–80%	Hb > 80%
Edinburgh ..	2–23 m.	262	5	23	42	30
Edinburgh	2–8 m.	143	4	15	40	41
Edinburgh .	9–23 m.	119	5	33	45	17
Aberdeen .	9–23 m.	298	15	23	49	13

A haemoglobin level of 86% ± 5 is widely accepted as the ideal for infants from 2 to 23 months. This figure was suggested by Helen Mackay (1933) from her examination of normal infants whose diets had been supplemented by iron. Haemoglobin levels of 80% or less would by this standard be considered subnormal. On this basis only 17% of the infants from 9 to 23 months in Edinburgh and only 13% of the Aberdeen infants had a normal haemoglobin level.

Mackay's figure of 86% seems to us reasonable, since haemoglobin levels of this magnitude and higher were commonly obtained in one of the Edinburgh clinics, where the mothers were particularly keen and intelligent. The higher average haemoglobin level noted in infants of 12 to 17 months examined at welfare clinics as compared with infants of the same age group in the wartime nurseries (Table II) could be explained on the basis of this observation.

The significance of the frequency with which anaemia is still found in infants cannot be overemphasized. The aetiological importance of low birth weight and infections was stressed by Davidson and Fullerton in 1938. The desirability of augmenting the iron intake at the sixth or seventh month in order to counteract the fall in haemoglobin which occurs when the hepatic stores of iron become exhausted needs special emphasis. At first, when mixed feeding has not been fully established, this may best be done by giving small doses of inorganic iron in an easily assimilated form. Later, when the change to mixed feeding has been completed, this may be best accomplished by increasing the intake of foodstuffs rich in available iron. A careful investigation of this problem by paediatricians is obviously required.

Children of Pre-school Age (2 to 5 Years)

A study of the graph shows that any advantage which the Edinburgh series has over the Aberdeen series in infancy is lost during the pre-school period. Thus on entering school at 5 years the Edinburgh children had an average haemoglobin of 81%, compared with an average figure of 87% for the Aberdeen series.

School Children (5 to 12 Years)

As in the case of the infants, a curve has been constructed for the haemoglobin averages of school children in Edinburgh, 1942, and is shown in the graph, together with the curve obtained of school children in Aberdeen, 1935. It will be seen that the number of children in the different age groups is much smaller in the Aberdeen series than in the present Edinburgh series. The Aberdeen figures were obtained from children of the poorest classes, and since the majority of them had haemoglobin levels of 90% or over, it was not considered necessary at the time to carry out further investigation in this age group. In Edinburgh, on the other hand, on completion of the survey of the first group of 197 children, only 9% were found to have haemoglobin levels of over 90% in spite of the fact that these children were in much better social circumstances than those in Aberdeen. Consequently it was deemed advisable to extend the survey to cover a larger group of individuals. A figure of 95% ± 5 selected by us as a standard of normality for healthy school children is based on our own experience, and coincides with the figure given by Whitby and Britton (1939).

The comparison shows that in Edinburgh, 1942, the haemoglobin level throughout this age period is considerably lower than in Aberdeen, 1935, the average difference for all ages being approximately 10%. In spite of this the children did not show obvious signs of malnutrition, and in fact the anaemia would not have been revealed unless haemoglobin estimations had been carried out.

It should be noted that the haemoglobin levels of the children reaching school age were found to be slightly lower in the Edinburgh series than in the pre-war Aberdeen series. Helen Mackay (1942) investigated a series of 364 children comparable in class with our present series. Her average figure for the age group 5 to 13 years was 80%, as compared with the Edinburgh figure of 80.3%. Thus in both these series there is seen to be a fall of approximately 10% from the pre-war Aberdeen figure of 90%.

The analysis of these three series of haemoglobin figures to show the percentage of children in various haemoglobin groups is given in Table VI. This shows that whereas in the Aberdeen series not a single child had a haemoglobin of less than 80%, almost half of the children in Helen Mackay's series and more than half of the children examined by us in Edinburgh had haemoglobin concentrations below that level.

The children and also the infants in the Aberdeen investigation were drawn from the poorest section of the community at a time when the unemployment rate was extremely high. The weekly income assessed on the basis of "man value"* averaged only about 11s. per head in Aberdeen, in contrast with the present Edinburgh assessment of the family income of 520 women examined at ante-natal clinics, which ranged from 24s. to 39s. per "man value" per week.

It will be appreciated that in peacetime economic status is the chief factor influencing the nutrition of individuals; in wartime, on the contrary, "rationing" and the difficulty in obtaining some unrationed foods constitute the chief limitations, which, broadly speaking, are operative irrespective of income. This is probably the explanation of the higher incidence of anaemia noted by us during the present year in spite of the high figures for "man value" recorded. In support of this conclusion it is significant to note that since obtaining the data already recorded we have examined the haemoglobin concentration of 134 school children aged 5 to 12 years who were pupils in an Edinburgh secondary fee-paying school and who were drawn from a higher social and economic class than the children considered above. The average haemoglobin level for this group was 80.7%, a figure almost identical with that obtained for the 389 working-class children. The percentage of children falling in the different haemoglobin ranges was also similar.

The frequency and degree of anaemia present in school children from working-class families in Edinburgh in 1942 as reported in this paper call for the most careful consideration by both local and national authorities. It is obviously desirable that during the period of active growth and mental development the incidence of anaemia should be reduced to the lowest possible level. This can be achieved by one of two methods or by a combination of both. The first consists in the provision of school meals which are appetizing, well balanced, and rich in foodstuffs with a high iron content. Intensive propaganda must be undertaken to induce a much higher proportion of children to partake of such meals. The need for such propaganda is evident in Edinburgh, where, although the numbers are gradually rising, only some 20% of children are at present taking school meals. The second method is by supplying iron at the schools in the form of a tablet or a mixture, or incorporating it in some article of diet universally eaten, such as bread.

Investigations are at present being undertaken in Edinburgh to discover whether the anaemia can be prevented and corrected by diet alone or whether a supplement of iron is required.

Summary

The haemoglobin levels have been estimated in 831 infants, pre-school children, and school children from working-class families in Edinburgh. The results have been compared with a similar series examined in Aberdeen in 1935.

After three years of war no significant change was found to have occurred in the haemoglobin levels of infants, but a fall has been demonstrated in the case of school children.

We wish to express our thanks to Prof. Charles McNeil, Dr. G. J Linklater, school medical officer, and Dr. T. Y. Finlay, medical officer for maternity and child welfare in Edinburgh, for the facilities and help afforded us by them during this investigation.

PLASMA PROTEIN STORAGE

BY

J. BEATTIE, M.D., D.Sc.

AND

H. B. COLLARD,* B.A.

Bernhard Baron Research Laboratories, Royal College of Surgeons of England

In a previous paper (Beattie and Collard, 1942) it was stated that after a moderate haemorrhage there was a significant movement of plasma protein into the blood stream. This conclusion was reached by demonstrating that the observed plasma protein concentration of the blood after haemorrhage was greater than a value calculated from the haemoglobin concentration before and after haemorrhage. Dr. Sharpey-Schafer has pointed out to us in a personal communication that the formula used was incorrect and gave expected values which were too high. He suggested the following formula:

$$\mathrm{p1} = \mathrm{p} \times \frac{1}{1 + \frac{1}{x}\left(\frac{\mathrm{H}}{\mathrm{H1}} - 1\right)},$$

where p1 is the plasma protein concentration to be expected at, say, 75 minutes after haemorrhage, p is that observed at, say, 30 minutes after haemorrhage, H and H1 the haemoglobin concentration at 30 and 75 minutes after haemorrhage, and *x* is the plasma volume % divided by 100 at 30 minutes after haemorrhage. Using this method of calculating the expected value for the plasma protein concentration, we found that we had overestimated the true expected value by varying amounts ranging from about 3 to 15%. Consequently the movement of protein into the blood stream after haemorrhage was, in fact, much greater than we had reported. We are grateful to Dr. Sharpey-Schafer for pointing out our error. This movement of protein observed in anaesthetized cats has been recorded in human subjects bled comparable amounts (Stead, 1940; Wallace and Sharpey-Schafer, 1941). The view was expressed by us that the amount of protein entering the blood was determined probably more by the state of the protein reserves than by any other factor. After plasma transfusions in normal animals there is some evidence of an indirect nature that a movement of plasma protein out of the blood stream may take place (Beattie, 1942). As this outward movement was not constant in all experiments it may well be that it, too, is determined by the state of the protein reserves.

The sites of these reserve stores of protein have not been determined with certainty, but Madden and Whipple (1940), in a review of the evidence, considered that the liver was probably the most important store, although they admitted that direct evidence from hepatectomized animals and perfused liver experiments is at best equivocal. It was decided, therefore, to study the effects of plasma transfusions on hepatectomized animals and of varying protein concentrations in the perfusing fluid in perfused isolated livers. In addition, it was thought that by giving repeated plasma transfusions to normal animals it might be possible to determine whether the plasma protein reserves could be filled up rapidly and so allow the building up of high plasma protein concentrations in the blood within a relatively short time.

---

* The "man value" figures obtained by us were calculated on the following basis: each member of the family was assessed according to age and sex in terms of one man as one unit, one woman as 0.8 of a man, and a child as 0.5 of a man

* Leverhulme Scholar, Royal College of Surgeons of England.

Methods

The animals used in all the experiments were cats anaesthetized with nembutal (50 mg. per kg. of body weight). They were heparinized during the experiments. Plasma used for transfusions, etc., was obtained from heparinized cats. The cells were separated immediately after the blood was withdrawn and the separated plasma stored at a temperature of 6° C.

Chemical.—Plasma proteins were estimated by the biuret method of Robinson and Hogden (1940) and haemoglobin by the alkaline haematin method of Wu (1922). Plasma volumes were determined by the dye method using T.1824 (Evans blue). Dye concentrations were estimated by a photo-electric colorimeter. A regression curve plotted from the dye concentrations in samples taken at 10-minute intervals was used to obtain the plasma volume before dye was injected (Hamlin and Gregersen, 1939). Deviations from the regression curve were used to estimate variations in plasma volume as described by the same authors. Fresh injections of dye at hourly intervals were given to check the values calculated from the regression curve.

Plasma specific gravities were estimated by the falling-drop method of Barbour and Hamilton (1926), and from these the plasma protein concentration was estimated by the formula suggested by Weech *et al.* (1936). These estimations were of value only in normal and hepatectomized animals, in which they checked closely with the values obtained by the biuret method. Plasma S.G. estimations are valueless in perfused liver experiments, as they show continued rises during the perfusions irrespective of changes in protein content (as determined by the direct biuret method). The substances or substance which gradually increased in concentration in the perfusing fluid were not determined, but were probably urea, lactate, or glucose, or a mixture of all. The *p*H of the perfusing fluid was not determined.

Physiological.—The livers for perfusion were removed after the animals had been bled rapidly from the abdominal aorta. An inflow cannula was tied in the inferior vena cava above the diaphragm. The common bile duct was ligated and a cannula tied into the gall-bladder in all except two animals which had small gall-bladders. The phrenic vessels were ligated close to the inferior vena cava, and the liver was then removed. It was placed on a cotton gauze sling, with the portal vein and hepatic artery free to drain through the gauze into a porcelain funnel. This was covered with a perspex lid through which projected the two cannulae. Perfusion was carried out in reverse, the inflow being through the inferior vena cava and the outflow through the portal vein. The perfusion pressure was maintained constant at 12 to 15 c.cm. above the upper surface of the liver by a reservoir fed by a pump which raised the perfusion fluid from the oxygenator. The outflow from the liver was passed into the oxygenator, where it fell on to a rotating perspex disk which threw the fluid on to the walls of a glass cylinder through which a stream of oxygen passed. The fluid collected at the bottom of the oxygenator, and from there was raised to the reservoir by a pump. The porcelain funnel and the oxygenator were immersed in water baths maintained at a constant temperature of 40° C. The temperature of the perfusing fluid was 36° to 38° C.

Hepatectomized animals were prepared by the one-stage method of Firor and Stinson (1929).

Observations

Repeated Plasma Transfusions.—Five animals (91, 92, 93, 100, and 106) were given repeated plasma transfusions. The results of these transfusions on the plasma protein concentrations are shown in Tables I to III. No. 91 was given 4 transfusions, each of 10 c.cm., at intervals of 30 minutes. In spite of the fact that the animal's plasma contained 8·3 g. per 100 c.cm., the transfusion of the relatively low protein plasma (6.84 g. per 100 c.cm.) caused a transient rise in the plasma proteins (8.64 g.), followed by a decline which brought the plasma proteins (8.06 g.) below the pre-transfusion level. A second transfusion of the same plasma produced no significant change in the protein concentration at the end of 29 minutes. A third transfusion of the same plasma produced a significant rise to 8.40 g. per 100 c.cm. in 29 minutes. The fourth transfusion, again of the same plasma, raised the protein level to 8.84 g. at the end of 45 minutes, and it remained at that level at the end of 60 minutes.

The changes seen in No. 92 resemble closely those in No. 91. This animal had an initial plasma protein concentration of 6.67 g. per 100 c.cm. It received 3 transfusions, each of 20 c.cm., at 45-minute intervals. The plasma transfused had a protein content of 6.05 g. per 100 c.cm. The first transfusion caused a transient rise in protein concentration to 7.24 g. in 16 minutes. The value had declined to 6.94 g. at the end of 41 minutes. The second transfusion produced a considerable rise to 7.72 g. in 10 minutes, which was maintained until the third transfusion was given. This caused a further rise to 7.99 g., and this level was maintained with some minor fluctuations for 55 minutes.

No. 93 was given 3 transfusions, the second 42 minutes after the first, and the third 118 minutes after the second. The first 2 transfusions were of 15 c.cm. and the third was 10 c.cm. The protein concentration of the transfused plasma was 7.14 g. per 100 c.cm. After a fall, the pre-transfusion level was almost regained 41 minutes after transfusion. The second transfusion produced no change in protein concentration, but the third caused a well-marked

rise to 9.22 g. in 15 minutes. This new level was maintained for a further 70 minutes.

In No. 100 the second transfusion was given 1 hour after the first, and the third 45 minutes after the second. The plasma transfused was, as in the previous experiments, lower in protein content than the animal's own plasma. The first transfusion caused a rise in protein content from 7.69 to 8.23 g. per 100 c.cm. in 25 minutes. There was a slight decline over the remainder of the first hour. The second transfusion produced no change in protein concentration, and the third likewise, except at the final sample taken 55 minutes after this transfusion, when the protein concentration rose slightly to 8.3 g.

The reaction to the first transfusion in No. 106 was almost identical with that observed in No. 91. The second transfusion, 1 hour later, produced a considerable rise in protein content (7.11 g. to 7.86 g. per 100 c.cm.) in 10 minutes. The protein content continued to rise slightly for a further 30 minutes. The third transfusion, 45 minutes after the second, again caused a rise (8.03 g. to 8.26 g.), which was maintained for 40 minutes. The plasma used for the first and second transfusions had a protein content of 6.46 g. per 100 c.cm., while that for the third transfusion contained only 5.88 g. The protein content of the animal's plasma was considerably in excess of that in the transfused plasma.

Perfused Isolated Livers.—These experiments fall into two groups: (i) 5 experiments in which no plasma was added after the start of the experiment; and (ii) 4 experiments in which plasma was added. The results obtained in the first group are shown in Tables IV and V. The changes in plasma protein concentration are given in Table IV. Table V is calculated after allowing for losses due to sampling. In the 2 livers (Nos. 150 and 154) perfused with low protein perfusing fluid there was a rise in plasma proteins. The increase is greatest in the liver perfused with the lowest plasma protein fluid (No. 150). No change was found in No. 153, which was perfused with a fluid containing plasma protein in the concentration of 6.23 g. per 100 c.cm. Livers perfused with fluid containing higher plasma protein concentration than 6.23 g. per 100 c.cm. (Nos 172 and 173) apparently removed protein from the circulation.

TABLE V

No.	Total Plasma Protein in Circulation at Start of Experiment A	Total Plasma Protein Lost by Sampling B	Expected Total Plasma Protein at End of Experiment C	Actual Total Plasma Protein at End of Experiment D	Difference between Cols. C & D as % of Expected Protein

73	8·53	0·60	7·93	7·24	−8·7

The second group again had experiments with low and high protein content in the perfusing fluid (Tables VI and VII). No. 164, perfused with a plasma containing only 2.7 g. per 100 c.cm., showed an increase in protein concentration over a period of 60 minutes of 3%. The percentage increase in concentration in the second hour was 13.4, although 1.31 g. of protein had been added. Over the whole 2 hours there was an increase in total plasma protein of 7.9%. No. 165, also perfused with fluid of low protein content, showed no significant change in concentration over a period of 50 minutes. When 1.10 g. of protein was added the concentration returned to its initial level about 1 hour later. Protein had been lost from the perfusing fluid. Perfusion with a much higher protein concentration in No. 167 led to a fall of 8.2% in concentration in 50 minutes. After 1.23 g. of protein had been added, the concentration returned to the starting level. The addition of 40 c.cm. of Tyrode's solution failed to produce any output of protein from the liver, and consequently the total protein at the end of the experiment was almost identical with that expected. The last experiment (No. 170) showed a rise in plasma protein concentration of 3.7% in 1 hour. The addition of 1 85 g. of protein increased the concentration by a further 3.9%. The gross increase in total plasma protein, however, exceeded by only 2.6% the value expected.

Hepatectomized Animals.—These animals were observed for a control period before giving plasma transfusions. The changes in their plasma protein and haemoglobin concentrations are shown in Table VIII. Of these, 4 animals (Nos. 147, 158, 162, and 168) maintained their haemoglobin concentrations within ±3% of the first value. An examination of the dye disappearance curve shows that their plasma volumes appeared to be constant within narrow limits. No observations of plasma volumes were made on No. 168. No. 161 showed a marked increase in plasma volume and a corresponding reduction in haemoglobin concentration. The plasma protein concentration did not fall parallel with the fall in haemoglobin concentration. No. 166 showed an actual increase in plasma protein concentration, with a reduction in haemoglobin concentration and a rise in plasma volume. Calculating the changes in total plasma proteins, it was noted that Nos. 147 and 158 showed no evidence of movement of plasma protein into or out of the blood. No. 162 showed a decline of 4%, which is probably significant. Nos. 161 and 166 showed evidence of movement of plasma proteins into the blood (Table IX).

After a known amount of plasma had been transfused into 4 animals the changes in haemoglobin and plasma protein concentrations were observed and plasma volume estimations made (Table X). An analysis of these results (Table XI) showed that 3 out of the 4 animals (Nos. 147, 158, and 162) lost protein in substantial amounts, and 1 animal (No. 161) gained over 5% plasma protein. Without placing too much reliance on the actual values, it is clear that plasma protein movement out of and into the blood stream does take place in hepatectomized animals

Discussion

After repeated transfusions with plasma of a protein content lower than that of the animal's blood, the plasma protein content showed significant rises in 4 out of the 5 animals, and a rise of doubtful significance in 1 (No. 92). Analysing these results, it can be seen from Table XII that 4 animals (Nos. 91, 92, 93, and 106) lost the major portion of the transfused fluid from the circulation. One animal (No. 100) lost about half the transfused fluid.

The plasma protein added to the blood was retained in the circulation in 2 experiments (Nos. 92 and 100), and considerable fractions of it left the circulation in the others (Nos. 91, 93, and 106). Presumably, the greater part of this "lost" protein entered the protein stores.

Retention of plasma protein in the circulation may be accomplished by increasing the concentration to a much higher level and by expanding the blood volume. In No. 92 the former factor is predominant, and in No. 100 the latter. The question may be asked: "What determines whether plasma protein moves from the blood or is retained in it?" It has been suggested (Beattie and Collard, 1942) that the state of the plasma protein stores may be the most important factor.

If this be the explanation, then we have to assume that the plasma stores in Nos. 92 and 100 were well filled and could accommodate no more plasma protein. Examining these experiments in some detail, the effects of the first transfusion of low protein plasma are of interest. Determining the total plasma proteins from the animal's and transfused plasma volumes and the plasma protein concentrations, this value is divided by the concentration observed at certain time-intervals, thus giving the plasma volume to be expected. Assuming that no plasma protein has entered the blood stream, the plasma volume of No. 92 at 10 minutes after transfusion ought to be 197 c.cm., which would mean that 18 c.cm. of fluid had disappeared from the blood. However, as the haemoglobin concentration had declined from 102.0 to 95.84, it is clear that such a movement of fluid could not have occurred. Plasma protein must therefore have left the plasma stores and entered the blood stream. The subsequent fall in plasma protein may be due either to movement of fluid into the blood or protein out of it. If the former were the cause, the haemoglobin concentration would show a continued fall; in fact, however, it rose slightly to 97.54 at 16 minutes and 97.84 at 26 minutes, and fell slightly to 97.0 at 41 minutes. It must be concluded that there has been a reverse movement of protein into the stores.

The second transfusion produced a similar effect. The plasma protein concentration rose sharply at 10 minutes and, after fluctuating at 16 and 26 minutes, fell slightly at 41 minutes. The haemoglobin concentration moved in the reverse direction, rising from 97.24 at 10 minutes to 100.1 at 41 minutes after transfusion. Flow and ebb of plasma protein from and into the stores must have occurred. The third transfusion showed clearly that the same events have taken place. As the haemoglobin 10 minutes after transfusion was identical with that at 55 minutes after, no substantial movement of fluid could have occurred. Hence the final rise in plasma protein concentration must have been due to the plasma protein added from the stores.

An analysis of No. 100 showed that the large loss of transfused fluid was shared equally between the three transfusions. The loss was rapid and complete within 10 minutes, as the haemoglobin concentrations at the 10-minute and subsequent samples after each transfusion were within 1.6% of each other. The changes in plasma protein concentrations do show, therefore, after the 10-minute samples, the ebb and flow of protein from the stores to blood and of blood to stores. The small amplitude of this tidal movement, coupled with the fact that the values for the plasma proteins are high, suggests strongly that this animal, too, had well-filled protein stores.

Saturation of the protein stores can be accomplished by repeated plasma transfusions. No. 93, after 2 transfusions, showed a final plasma protein concentration of 8.57 g. per 100 c.cm. 56 minutes after the second transfusion, identical with the value at the start of the experiment. A third transfusion raised the level to 9.22 g. in 15 minutes, and maintained it there for a further 20 minutes. In No. 91, at 29 minutes after a third transfusion, the plasma protein concentration was only slightly higher than the level before the first transfusion. The fourth transfusion raised the level significantly and maintained it there for 1 hour. Saturation of stores was completed by the second transfusion in No. 106, and a subsequent transfusion raised the level still higher and maintained it for a further 40 minutes.

In view of Madden and Whipple's (1940) opinion that the liver is an important site for the storage of protein, it seemed possible to test on this organ the suggestions outlined above. Madden and Whipple envisaged a steady state, or ebb and flow, between the plasma proteins and those in body cells. That idea presupposes two reservoirs of protein, one in the blood stream and the other in reserve in tissue cells. A state of equilibrium between the two reservoirs tends to appear, and the speed with which it is accomplished will depend on the "gradient" between the "levels" of protein in the tissue cells and that in the blood stream. If the level of available plasma protein is low in the tissues, then high degrees of hypoproteinaemia may persist. On the other hand, a high level of protein in the blood stream will only remain high if the protein reserves are also high.

The isolated liver experiments show clearly that the liver can mobilize and throw into the perfusing fluid quantities of plasma protein (Tables V and VII, Nos. 150, 154, 164). The stimulus for this production is obviously the low plasma protein concentration of the perfusing fluid. There is, too, in these experiments a correlation between the degree of "hypoproteinaemia" and the rate of plasma protein production. One experiment (No. 165), in which the plasma protein concentration was low, showed no change in concentration over 50 minutes. It may be presumed that the reserves were also low in this liver, and this is supported by the fact that the addition of 1.10 g. of plasma protein produced a temporary rise and then a disappearance of all the added protein inside 1 hour. Equilibrium between stores and circulating protein seems to be suggested in one experiment (No. 153). Protein was lost from the perfusing fluid in two experiments (Nos. 172, 173). The loss was greater in the experiment with the higher plasma protein concentration.

When plasma was added to the perfusing fluid about 1 hour after the experiment had begun, the results obtained again seemed to depend partly on the state of the reserves and partly on the concentration of protein in the perfusing fluid. One liver (No. 164) showed a continuing output of protein after the addition of plasma, while another (No. 165), perfused under precisely the same conditions with a perfusing fluid almost identical with that used in No. 164, showed a loss of the added plasma protein. Previous to the addition, this liver had added no protein to the perfusing fluid, and hence it can be presumed that the reserves in this liver were low. Another liver (No. 167), perfused with a rich plasma protein fluid, lost protein from the circulating fluid. The added plasma protein produced a rise in concentration, and presumably all of it remained in the perfusing fluid. The addition of Tyrode's solution merely diluted the perfusing fluid without producing any further addition of protein. The remaining experiment (No. 170) showed a small rise in concentration before plasma was added. The added protein remained in the perfusing fluid, although from the values obtained for protein concentration it would appear that there was at first a movement out of the perfusing fluid, followed by a movement in the reverse direction.

There can be no doubt, therefore, that the liver does behave as a "store" for plasma protein. It remained, however, to determine if it was in fact the only store. Hepatectomized animals were prepared and after variable periods given plasma transfusions. Two animals (Nos. 147, 158) showed no change in total plasma proteins before they were given a transfusion. One (No. 147), at 70 minutes after the transfusion, showed an appreciable loss of protein out of the circulation. The other (No. 158) lost a greater amount in 40 minutes. Another animal (No. 162) had lost some protein before transfusion and continued to lose an even greater quantity afterwards.

These results may indicate a movement of protein into other stores, but they are not as convincing as evidence of movement from such stores into the blood. Such evidence is provided by Nos. 161 and 166. Over a period of 30 minutes, while blood dilution was proceeding, No. 161 raised its total plasma protein by a small but significant amount. No. 166, over a period of 45 minutes, also while blood dilution was proceeding, raised its total plasma protein by 11% over the expected value. No. 161 continued to add protein to its circulation after a plasma transfusion at about the same rate as before transfusion,

The evidence from these experiments does suggest that plasma protein leaves the blood stream in hepatectomized animals in quantities greater than might reasonably be required for normal metabolism, and, conversely, these animals seem to possess some source of plasma protein other than the liver.

The speed with which protein may enter or leave the blood stream or perfusing fluid lends support to Whipple's view that protein can move as such from cells to plasma, and plasma to cells, as the need arises. It is clear, too, that the storage mechanism is not capable of dealing with large quantities of excess protein added to the blood. A rising plasma protein concentration after repeated plasma transfusions is an indication of saturation. The site of the protein stores cannot be pinned down exclusively to the liver. Whether all body cells can contribute protein to the blood stream with the facility with which they apparently can withdraw it has yet to be decided.

Summary

Repeated plasma transfusions show that the plasma reserve stores may become saturated with protein and that further transfusions will lead to a rising plasma protein concentration and plasma volume.

The liver can add to or abstract plasma protein from the blood. The direction of the movement depends on the state of the liver's reserves and the plasma protein content of the blood.

Protein stores from which plasma proteins may be derived, or in which plasma protein can be stored, exist apart from the liver.

We wish to thank our technical staff for the assistance they have given in carrying out these experiments.

TONSILLECTOMY BY GUILLOTINE AND DISSECTION

BY

T. B. JOBSON, M.D., B.Ch.

Controversy regarding the best method of enucleating tonsils is ever with us. Even now there are a great many relevant points that are not appreciated by the majority of doctors and some specialists. As one who has had to perform some 15,000 of these operations by both methods, I feel that analysis of this controversy may be of interest.

Taking the guillotine operation, let us inquire why such a lot of bad work is done by this method and why it has got a bad name in many quarters. The modern "reverse" technique was introduced in 1910 by Whillis and Pybus of Newcastle. They described their results in 200 cases in the *Lancet*. Very little notice was taken of their work in this country, but in America the idea was adopted by Sluder, who with the proficiency of practice brought his skill in the method to a very high level. In fact, he claimed that his results showed 99.6% of complete enucleation in children. His advocacy of the method brought back to this country its use by surgeons who appreciated the improved technique and who had opportunities of gaining skill by practice.

Reasons for Poor Results with the Guillotine

It may be asked why the results achieved by the guillotine are so variable. Restricting the discussion for the moment to children, let us inquire why some doctors firmly believe that a tonsil cannot be completely removed with the guillotine. Indeed, a good many of the public (instructed by their doctors, no doubt) are of the same opinion. There is some justification for this view, for undoubtedly a great deal of bad work is done with the guillotine. Now, why should this be? If Sluder can produce 99.6% of complete enucleations, the method cannot be at fault. My experience assures me that it is not at fault. Why, then, does not the method yield such excellent results universally? Several reasons suggest themselves.

Many doctors imagine that tonsils can be removed by anyone as soon as he can write M.R.C.S. or B.Ch. after his name. They think that tonsils are like ripe strawberries, ready to be plucked off. They are confirmed in this opinion when two or three come out successfully. The fact that the fourth or fifth is badly done does not shake their complacency. But this means 20% bad results—enough to give the method a bad name. The fourth is perhaps a "mushy" tonsil. The lymphoid tissue strips off, leaving the capsule behind with remnants of tonsil tissue. The next may be one with a horizontal cleft near the lower pole, inviting the ring of the guillotine to be placed in the cleft, and so leaving a lower pole. Again, perhaps the capsule is thickened and there is difficulty in invaginating the tonsil into the ring of the guillotine. Too much pressure is used with the finger, and it perforates the anterior pillar. The pitfalls are many and are not realized at first.

The bad results are not noticed by the parents. The surgeon "gets away with it." In other operations, such as appendicectomy or hernia, a bad one will become manifest immediately, so it follows that the surgeon learns to do these under supervision and does not attempt them until he is competent. The analogy with golf is rather apt. The member who has just been elected sees the professional tee up a ball and drive it down the fairway 250 yards. It looks so simple, but the beginner does not find it so. He has to practise and practise; after a time he gets to the stage of missing one shot in four, but his handicap is then only 18. He has to have lessons and do more practice before his handicap gets down to single figures. Only a few reach the scratch mark—those who are endowed with a fine touch and good muscular co-ordination. So it is with guillotine tonsillectomy. It requires good "hands" to start with and long—very long—practice to achieve anything like 100% success. Also, the surgeon must be able to use his left hand as well as his right.

Another cause of poor results is that at many hospitals tonsil operations are left to the house-surgeons unsupervised. They do their best, but their results cannot reach the desired 100% goal in their short period of residence, and their successors repeat this unsatisfactory process. There is another reason for the odium cast on the guillotine. Many of our surgeons who restrict themselves to the dissection method and who never had the opportunity or desire to persevere with the long practice required for expert guillotine work are apt to condemn the method and noise it abroad that the only satisfactory method is by dissection. To justify this they point to some of the bad results outlined above.

Finally, the removal of a child's tonsils and adenoids in a minute or two with the guillotine is a much less spectacular operation than a set dissection lasting ten times as long. The parent may think he is getting better value for his money for the longer operation, which is not always the case.

I have nothing to say against the dissection operation. It is an excellent method, and in adults is, I think, the method of choice. It is more easily learned, and a good many house-surgeons learn it fairly well in their six-months period—although further practice is required before they become experts.

The Methods compared in Adults

So far I have dealt with the guillotine operation in children. It may be of some interest to compare the value of the two methods in adults. To get some evidence on this point I have during the last two years tried out the method of dissecting one tonsil and guillotining the other—alternately right and left. Analysis of the first 100 cases showed that 11 were unsuitable for the guillotine. These were cases of very flat tonsils, some which had had a previous operation, some with a very thickened capsule, the result of quinsy, etc. In the other 89 cases observation notes were made on: (1) haemorrhage, (2) appearance of the tonsil bed, (3) after-pain.

The results showed practically no superiority of either method. The desired slit-like bed was more often achieved by the guillotine. Those requiring a ligature were about equal. My conclusion, then, is that the guillotine method is not applicable to all cases in adults—and also that it requires a great deal more skill to get good results than is the case with children. The dissection method is therefore, I consider, the method of choice in adults. In this method each surgeon develops his own technique. One point I would like to emphasize, and that is the importance of dissecting up the mucous membrane from the pillars and upper pole and then "delivering" the tonsil from underneath this fringe of mucosa, which will then form a covering for the edges of the pillars. This procedure greatly lessens after-pain and prevents cicatricial contraction of the pillars.

It is interesting to recall that Whillis and Pybus in their first 200 cases claimed only 65% of perfect tonsillectomies. Compare this with Sluder's results a few years later. In 1924 I published a paper on this subject.[1] In this I estimated the number of completely successful results at 95%, but now I believe even this is too low. By immediate inspection of the bed and examination of the tonsil removed it can be ascertained if a fragment has been left. This can be dissected out in a few minutes. Such a necessity is very rare, but its recognition is important if we aim at perfect results.

It must not be thought that tonsillectomy by dissection is always easy. The difficult tonsil for the guillotine is difficult for dissection, and the results by this method are not always perfect. As in every operation, skill increases with practice, and skill is more rapidly gained in dissection than in the guillotine method. Serious bleeding does not often occur, but it can be very alarming and indeed dangerous. The surgeon therefore must be competent to deal with haemorrhage in the tonsil bed. Finally, our aim must be "to remove the tonsil, the whole tonsil, and nothing but the tonsil." The guillotine is more likely to fail in the second, dissection to err in the third, of these aims.

Anaesthesia

Our routine for adults is intratracheal ether with packing of the hypopharynx. This helps to prevent the possibility of inhalational pneumonia or lung abscess. For the guillotine operation in children ethyl chloride is used, and for dissection in children a short ether anaesthesia. The children are given 1 to 2 grains (according to age) of seconal an hour before operation, and one hopes that this will obliterate any memory of the operation. Again we find the improvement in statistics since our specialist anaesthetist has been appointed for this purpose. Many years ago, when changing house-surgeons gave the anaesthetics, we had two or three fatalities, but for five years since this anaesthetist has been doing the work we have had none.

---

[1] *Practitioner*, 1924, 113, 100.

The conclusion is that the appointment of special surgeons and anaesthetists has raised the standard of tonsillectomy to a very high level.

ATYPICAL "INFLUENZAL PNEUMONIA" AT A SCHOOL

BY

H. G. J. HERXHEIMER, L.R.C.P.&S.
Medical Officer, Highgate School, Westward Ho

AND

A. J. McMILLAN, M.R.C.S., L.R.C.P.
Tuberculosis Officer, N. Devon

During a period of three months, March to May, 1942, a small but peculiar epidemic occurred at the evacuated section of Highgate School, at Westward Ho. The history of the outbreak may be considered worth recounting.

Symptomatology

The outbreak had the external appearance of an influenza. The temperature at the start was seldom more than 102°, and remained so for one or two days; it then dropped to between 99° and 100°, and remained there from 3 to 7 days. The symptoms, in the main, consisted of a mild headache or a sore throat; apart from the temperature the only positive finding was a pharyngitis. After a week or less the temperature became normal and the symptoms cleared up. After a further period of 2 to 7 days, however, the temperature suddenly rose again, in one or two cases quite steeply, and remained above normal for some days, in a few instances for a fortnight or even longer. During this period a cough often appeared, and in a few cases a few very faint crackling rales were heard over a localized area of one lung.

In these cases radiological examination of the chest was carried out, but, owing to the long distance from the hospital, this was possible only after some delay, when the journey could be undertaken without too much risk. In all these cases (7), with one exception, a typical *x*-ray picture was found: an area of one lung-field was distinctly blurred—frequently the lower third of the right lung-field—the movement of the corresponding dome of the diaphragm was impaired, and in one case there was a small effusion in the costophrenic angle. The homogeneous shadow was similar to that of a resolving area of pneumonic consolidation. Later control radiographs revealed that this diffuse shadow had disappeared and the lung-field showed no abnormality. In two cases, however, a recrudescence occurred after an interval of 4 to 6 weeks, with exactly the same symptoms, and repeated radiographs showed that the previous pathological shadows had become more marked.

In all, there were 28 cases of "influenza" during the same period, which may, of course, have belonged to quite different types. In one group of about 10 cases the symptoms were very slight, and lasted a few days only. Of the remainder, 12 cases showed the typical features described above, consisting of a two-stage illness, separated by an afebrile interval of apparently complete health.

In this second group 7 cases were radiographed; 6 of them showed residues of a diffuse inflammatory process in an area of one lung. The following history is typical of one such case:

A schoolboy aged 14. No previous history of importance. During Easter holidays, at the beginning of April, 1942. he was in bed with a mild influenzal attack, slight unproductive cough, and temperature just over 99°, which settled down in a week. He was quite fit for a month, but on May 14 developed a febrile cold again, and the temperature rose to 99.8°, but was normal again on May 17 and 18. On May 19 the temperature was 102.6° in the morning; sulphapyridine was given 4-hourly and it fell to 99.2° in the evening. At this time some crepitations were heard over the right lower lobe behind. By the 21st the temperature had settled to normal and remained so.

X-ray examination, May 26 (A. J. M.).—"Screening: Upper lung-fields light up brightly and evenly. There is some increased density at inner angle of right dome of diaphragm, and outer sulcus of same is blurred. Film: This confirms screening report. There is very slightly diminished translucency over right upper lung-field compared with left. There is some increased density and striation at inner angle of right base, and filling up of outer sulcus of right dome. The *x*-ray appearance suggests a residual inflammatory process at right base following influenza." June 9, screen only: outer sulcus of right dome of diaphragm has now cleared.

In this case the administration of sulphapyridine appears to have speeded up recovery; but other cases, not treated with it, took a similar course, and its value in this type of illness must therefore remain doubtful.

Conclusions

Unfortunately, extensive bacteriological investigations have not been possible, and we cannot say to what type of pneumonia these cases belonged. Nevertheless, their publication seems to us desirable for the following reasons: (1) The course of the illness is not typical for an influenzal pneumonia; it might even belong to another group of virus disease. (2) As no other cases have been noted in the district among adults, it may be that the illness attacks mainly adolescents. (3) Owing to the mildness of the illness and the absence of any marked symptoms, it will rarely lead to hospital treatment, and its special characteristics and complications may easily be overlooked; the attention of the practitioner should therefore be drawn to it.

Medical Memoranda

An Unusual Case of Injury to the Female Urethra

Injury to the female urethra apart from childbirth or operative procedures is very uncommon. This is presumably because of its comparatively well-protected position and shortness. In the male, on the other hand, injury to the urethra is more frequent and it is well known that it is usually caused by falling astride an object. In the case here described an injury was sustained by a woman which we consider to be comparable to the well-known injury to the male urethra. Interest is added to the case when it is learnt that the patient was wearing trousers at the time of the injury.

Case History

A married woman aged 38, a unipara, had just returned from her work as a milk roundswoman, and was putting up black-out curtains in her home, climbing on to the window-sill to do so, when she slipped and fell astride the back of an ordinary wooden chair. Her fall was fairly heavy: she was apparently standing about 4 feet above the chair when she slipped. It appears that she came down so that a projecting knob on the corner of the chair struck the anterior part of the vulva and anterior vaginal wall. She felt an immediate "numbing" pain, and after a few seconds found that she was bleeding profusely

On admission to Hendon Cottage Hospital there had been a fair amount of haemorrhage, which was seen to be coming from an extensive tear in the anterior vaginal wall and vestibule. This tear extended transversely across the anterior vaginal wall at the exact level of the urethral orifice and each end of the tear split into two directions, one running backwards and upwards into the vagina, and the other forwards on to the vestibule. There was also considerable bruising of all the parts, and a large haematoma had formed under the anterior end of the left labium. There was no sign of the urethral orifice.

Under an anaesthetic given by one of us (R. H. C.) the patient was put in the lithotomy position and the tear carefully examined (D. J. N. S.). It was then seen that the urethra had been torn away from the vaginal wall and was lying free in nearly all its length in a space between a flap of anterior vaginal wall posteriorly and the posterior surface of the symphysis pubis in front. The free lower end of the urethra was caught with forceps, brought down, and a catheter passed. Clear urine came from the catheter, and saline was injected into the bladder and the volume checked. It was then obvious there had been no injury to the bladder. A plastic repair was done, and the mouth of the urethra sutured as nearly as possible in position, a stitch being placed to anchor it to the periosteum of the postero-inferior surface of the symphysis pubis. An in-dwelling catheter was left in, and the vagina packed with mercurochrome gauze.

Recovery was rapid. The pack was removed in 24 hours and the catheter in a week. The bruising and haematoma of the vulva rapidly disappeared and the patient was discharged after a fortnight. There was complete control over micturition, no stress incontinence, and the vagina healed without stenosis.

Commentary

The features of this case are the rarity of the injury and the circumstances of its occurrence—exactly similar to the way in which rupture of the male urethra is produced. What is very interesting is that the patient was dressed in trousers at the time of the accident. In addition she had thick underclothes on beneath the trousers, which were themselves made of thick serge, so that the injury was produced entirely by contusion just as the male urethra is ruptured. It is probable that had the patient been wearing a skirt she would not have been injured, and clothing may be a factor in the prevention of injuries to the female perineum. It raises the question, of course, as to whether surgeons must be prepared to see such cases, as fashion dictates that increasing numbers of women shall wear trousers!

R. Hunt Cooke, M.D., M.R.C.P.,
Medical Superintendent, Hendon Cottage Hospital.

Surgeon, E.M.S.

Persisting Epilepsy following Shock Therapy

The rare occurrence of spontaneous fits over a long period following shock therapy is illustrated by the following case.

Case Report

The patient, a man aged 22, first came under my care on Sept. 19, 1940. He had had convulsions at intervals for six months when 1 year old. From 7 to 14 he suffered from an illness described as chorea—he now shows physical signs consistent with a diagnosis of a compensated rheumatic heart lesion. At 20 he had his first mental breakdown, a depressive illness lasting six months. A year later he was diagnosed as a schizophrenic, and had spent a further year in mental hospitals and been treated with ten therapeutic convulsions when he came under my care. He was dull and retarded, but suspicious, moody, and freely hallucinated—a typical "chronic" schizophrenic. Blood examination showed 4.9 million reds, haemoglobin 75%, and sedimentation rate normal; the urine was repeatedly found clear and normal. From Sept. 23, 1940, to Jan. 2, 1941, he was given a course of insulin therapy, the coma dose rising from 80 to 952 units, and 19 comas followed 63 injections. The course was complicated by occasional severe coma fits and after-reactions. Treatment by T.A.B. vaccine was then tried, 13 intravenous doses, rising from 5 million to 750 million bacilli, being given between Jan. 4 and Feb. 21, 1941. On Jan. 19 a spontaneous fit occurred, and two more were recorded in January and four more up to Feb. 15, accompanied by mental improvement, when 1 grain of phenobarbitone each night was prescribed. This controlled the fits; but the mental state relapsed, and the drug was discontinued on Feb. 28. A fit occurred on March 3, 1941, and six in March altogether, with five more by April 15, when he left my care considerably improved mentally.

The firm impression gained was that his spontaneous fits controlled his schizophrenia, and this continued satisfactorily until July, when further phenobarbitone therapy stopped the fits and heralded another mental relapse. He came under my care again; the medication was terminated and one electric convulsion given, and this was followed by one or two spontaneous fits a week, with mental improvement. Inquiry on Dec. 12, 1941, elicited the information that the fits continued and he remained cheerful and sociable, occupying his time rug-making and playing the piano. A further report dated June 28, 1942, states that he still has one or two fits weekly, and that epanutin was tried and stopped the fits; but it made him mentally worse and had to be abandoned. His mental condition, all things considered, remains good.

Reviews

PAEDIATRICS

Nutrition and Chemical Growth in Childhood By Icie G. Macy, Ph D Volume I: Evaluation (Pp 432; illustrated $5.00 or 27s 6d.) Springfield and Baltimore: Charles C. Thomas; London: Baillière, Tindall and Cox 1942.

Management of the Sick Infant and Child By Langley Porter, M.D, B S., and William E Carter, M.D. Sixth revised edition. (Pp. 977; illustrated 57s. 6d) London, Henry Kimpton. 1942

A Handbook on Diseases of Children, including Dietetics and the Common Fevers By Bruce Williamson, M.D., F R.C.P. Third edition. (Pp 364; illustrated. 12s. 6d., plus 6d. postage) Edinburgh: E. and S Livingstone 1942.

Wartime Food for Growing Children. Issued for the Ministry of Food by the Ministry of Information. (Pp 25. 4d, or 13s. 4d. for 50 copies.) London: H M. Stationery Office. 1942.

Dr. Icie G. Macy has provided a valuable collection of facts in her *Nutrition and Chemical Growth in Childhood*, the first volume of which is entitled "Evaluation." Many years of experience, wide reading, and the collaboration of colleagues have gone to the making of this book, which is essentially a record of the scientific methods required and the results obtained in the study of nutrition in childhood with particular reference to the biochemical aspect. A second volume, to be called "Interpretation," is promised for next year. Meanwhile the paediatrician will be grateful for a collection of valuable data, and especially for the results of balance experiments conducted by a method of rapid micro-analysis which gives results quickly after the collection of samples and opens the way to a wider use of this method of studying nutritional problems. The publication of this volume has been made possible by "The Children's Fund of Michigan" and it is introduced in a foreword by Dr. Hugo A. Freund, who is president of the board of trustees of the fund.

Another notable paediatric publication from the United States of America is the sixth edition of the well-known *Management of the Sick Infant and Child*, by Prof. Langley Porter and Dr. William E. Carter. This is a product of the California University Hospital, and continues in its extensively revised form to be a thoroughly practical account of the care of the sick child. Details of treatment are stressed throughout, and the method of approach in the early chapters through the dominant symptom—e.g., "vomiting," "diarrhoea," "haemorrhage"—has much to commend it. Both authors are widely experienced, and they have the fortunate help of many colleagues in certain sections of the book. The sections on therapeutic procedures are of particular value.

The third edition of Dr. Bruce Williamson's little work—*A Handbook on Diseases of Children*—also bears marks of extensive revision, especially that necessitated by the introduction of the sulphonamide drugs. But it is by no means up to date, for there is no mention of gentian violet for threadworms, of atebrin for lamblia, or of modern views on icterus gravis neonatorum. The dangers of raw milk (even the higher grades) are not sufficiently stressed.

Wartime Food for Growing Children is another collection of Dr. Charles Hill's informal broadcasts in the popular "Kitchen Front" series. The information imparted is essentially sound and practical, and practitioners would be well advised to recommend it to parents. The value of suet in puddings (when available!) is perhaps underrated, but critical reading has failed to reveal any other departure from modern paediatric standards. The broadcasts read as well as they sounded.

THE VITAMINS

Chemistry and Physiology of the Vitamins. By H. R. Rosenberg, Sc.D. (Pp. 674. $12 00 or 72s) New York: Interscience Publishers Inc: London: Imperia Book Company.

Dr. Rosenberg was tempted at first to write one book on the vitamins and hormones, since the two classes of compounds have so much in common. The task, however, proved too big and he wisely confined his effort to an account of the vitamins only. He has made a praiseworthy search of the literature, giving exact references to more than 3,000 original papers in footnotes on the appropriate pages, with an index to these references at the end of the book under the names of authors arranged in alphabetical order.

The subject-matter is systematically arranged in chapters on vitamins in general, the groups of vitamins A, vitamin B_1 (thiamin), vitamin B_2 (riboflavin), vitamin B_6 (pyridoxin), nicotinic acid (nicotinamide), pantothenic acid, inositol, para-aminobenzoic acid, vitamin C (ascorbic acid), the group of vitamins D, the group of vitamins E, vitamin H (biotin), the group of vitamins K, vitamin P, non-identified vitamins (including B_3, B_4, B_5, B_7, B_8, B_c, B_p, J, L_1 and L_2, M, T, U, folic acid, growth factor for *Lactobacillus casei*, grass juice factor, mouse factor, anti-pernicious-anaemia factor). An appendix is devoted to the vitagens (including essential fatty acids, amino-acids and carbohydrates, and choline and related compounds). There is also a patent index giving the patent number, date, patentee and assignation, and claims of about 1,200 patents dealing with vitamin preparations. Each chapter has sections, where possible, on nomenclature and survey, chronology, occurrence, isolation, properties, constitution, synthesis, industrial methods of preparation, biogenesis, specificity, determination, standards, physiology of plants and micro-organisms, animal physiology, avitaminosis and hypovitaminosis, and requirements. Provitamins A and provitamins D are treated nearly as fully as the corresponding vitamins.

Dr. Rosenberg has dealt most fully with the chemistry of the vitamins. Syntheses are clearly explained, and are lavishly illustrated by structural formulae. We would like to have seen described Bourdillon's work on the preparation of pure calciferol from the irradiation products of ergosterol; it is scarcely mentioned. However, the omissions we most regret on behalf of readers of this *Journal* are the accounts of clinical trials with the vitamins. There is no mention of Dr. Martha Elliott's comparison of the efficacy of vitamins D_2 and D_3 with regard to the curing and prevention of rickets in young children (the most convincing evidence of their equality yet published); or of Dr. Helen Mackay's work on the influence of a shortage of vitamin A on young children; or of Mellanby's work on the influence of vitamin A on convulsive ergotism and lathyrism, and on overgrowth of bone, which may affect parts of the nervous system (especially the auditory nerve); or of his solution of the toxamin problem. There is only one sentence (a very inadequate one) dealing with Lady Mellanby's work on the influence of vitamin D on the development of caries, and none on her work on gingivitis. There is no mention of the use of cod-liver oil in wound-healing, though whether the benefit is due to vitamin A is uncertain. The biological standardization of the vitamins is treated very scrappily, some of the work referred to being obsolete, and there is no statement of the general principles underlying the methods now accepted. In spite of these defects, however, much remains in the book to render it acceptable to workers on the subject, and many parts of it will stimulate readers to make therapeutic trials of the vitamins, for they can scarcely do harm and they may bring about results of inestimable value.

"THE MYSTERY OF THINGS"

The Circle of Life. A Search for an Attitude to Pain, Disease, Old Age and Death. By Kenneth Walker (Pp 158 7s 6d.) London: Jonathan Cape. 1942

Lotze said that a philosophical system is an attempt to justify a fundamental view of things which had been adopted early in life, and Mr. Kenneth Walker, as a child, sensed the unity of all life. Unlike Wordsworth, that vision of his has not faded but grown with the years. The present parlous state of civilization is compelling man to take a humbler view of his position in the universe so that he is more inclined to admit the interdependence of all living things. In *The Circle of Life*, which may be regarded as a sequel to his *Diagnosis of Man*, Mr. Kenneth Walker essays to help towards an understanding, though naturally not a complete solution, of the problems of disease, pain, suffering, old age, and death. His conclusion is that the meaning can only be found if the subject be examined from the standpoint of the whole aggregate of life on the earth. A disease caused by a pathogenic organism instead of being a meaningless accident is then seen to be an inevitable consequence of the conditions obtaining in organic life. Bacteria can be allies as well as enemies; indeed, "micro-organisms form, as it were, the base of a living triangle, the two sides of which are the vegetable and animal worlds." In his survey he has many interesting things to say: thus "we need not question the purposive action of fear, because in excess it defeats itself"; "life cannot be measured in terms of years but only in terms of inner experience"; "longevity is not a question of miraculous draughts or diets or hormones or grafts, but of right living, both of the body and of the mind"—a valuable comment this, from one with professional experience.

"Man," said Sir Thomas Browne, "is the great Amphibium", he dwells in two interpenetrating worlds—the visible one of living matter, the invisible one of the spirit. As is well known, Mr. Kenneth Walker has for some years found a harmony for this in Oriental philosophy. He recognizes, however, that "a branch of knowledge cannot be isolated from Eastern thought and grafted on to a culture which is entirely foreign to it"; but as "Eastern and Western people barter the products of their industry . . . surely the time has come when with even more mutual profit they can exchange the products of the mind." Yet even his customary lucidity leaves us with but a vague and unsatisfying impression of Eastern philosophy. His discussion of "occult" phenomena naturally includes a consideration of the time-space continuum, and we were delighted to see his reference to Dr. E. A. Abbott's parable *Flatland*, which, published more than 50 years ago, brought home in a simple form the lesson that our minds are inevitably limited to three-dimensional conceptions.

Mr. Kenneth Walker deserves our thanks for a book at once stimulating and comforting. His medical experience enables him to rob death of much of its terrors for the uninformed. He devotes some space to the consideration of various theories about the hereafter. As to this we do well in following Shakespeare, one of whose greatest characteristics, according to Keats, was his capacity for "being in uncertainties, mysteries, doubts, without any irritable reaching after fact or reason."

Notes on Books

The 28th edition of *Gray's Anatomy* is stated to have been "produced under conditions of unprecedented difficulty"; the editors, Prof. T. B. **Johnston** and Dr. J. **Whillis**, however, with the assistance of Prof. F. Davies—the digestive system—and Dr. Denny Brown—the nervous system—have succeeded in overcoming all hindrances and have added much new matter which is of importance from the purely scientific and the practical standpoints, more particularly with regard to the sections dealing with development, myology, neurology, and the ductless glands. Many new illustrations have been added, including *x*-ray plates, by Cairns showing the position of the cerebral ventricles; Allison, the course of the parotid and submandibular salivary ducts; and Grout, a cholecystogram. An interesting memoir of Prof. Howden, who, succeeding Pickering Pick, was editor of *Gray's Anatomy* for 27 years, is contributed by the senior editor of the present volume. Prof. Howden was specially interested in the central nervous system and sense organs, the description of which, more particularly of the internal ear, is largely founded on his personal observations. The present editors may be congratulated on raising still further the high standard of utility and accuracy of previous editions, and there is no doubt that the popularity of *Gray's Anatomy* will continue as of yore. Longmans, Green and Co. are still the publishers, and the price is 60s.

In *Health for the Young* (George Allen and Unwin, 6s.), written for the lay public, Dr. **Lindsey Batten** displays his customary robust common sense. He could have chosen as his text, "It is not the function of the doctor to suggest ill-health," nor for that matter of anyone else, for (as he rightly points out) advertisements of patent remedies would convey the impression that health is a thing that can only be precariously maintained. "With the decline of faith in a benevolent Providence and the countervailing rise of faith in Science goes a quite unjustified disbelief in the power of living organisms to right themselves." His hard hitting at the prevalent fads and cranks of the day is refreshing, and his practical hints on the maintenance of health and the provision of an enjoyable life for the young should prove decidedly helpful.

No. 4 of Vol. 13, dated March, 1942, of the *Index to the Literature of Food Investigation* has been published by the Department of Scientific and Industrial Research at 4s. 6d. The items run from Nos. 1454 to 1939. Those who wish to obtain this *Index* regularly should send orders direct to the Sales Office, H.M. Stationery Office, York House, Kingsway, W.C.2, or to any bookseller.

"WAR AND THE ADVANCEMENT OF SOCIAL MEDICINE"

SIR WILSON JAMESON'S HARVEIAN ORATION

The Harveian Oration—the only one of the lectures of the Royal College of Physicians of London to be given this year in public session—was delivered on October 19 by Sir Wilson Jameson, Chief Medical Officer of the Ministry of Health. The President of the College, Sir Charles Wilson, was in the chair.

Sir Wilson Jameson began by remarking that William Harvey's life was cast in times of national stress like the present. He was a boy of 10 when the Spanish Armada came up the Channel, and at the age of 64 he was caught in the travails of the Civil War. Such times had always been followed by periods of great social change. The Napoleonic wars furnished a convenient first example. After them came the first Factory Acts, the abolition of slavery in the British Empire, the beginnings of elementary education, and the social emancipation brought about by the reform of Parliament. After the Crimean War, the heroine of which was Florence Nightingale, with her reforms of Army hygiene and nursing, came the growth of liberalism in politics, a new apprehension of the meaning of social justice, and, in hygiene, the beginnings of State medicine.

The South African War touched the conscience of England, partly because of the disclosures concerning the physical unfitness of many Army recruits, partly because of the excessive mortality from disease in the field, and partly because of the conditions in the concentration camps for Boer women and children. The demand for social change was faced in the new Parliament of 1906. The immediate consequences were the provision for feeding, physical training, and medical examination of school children, the beginnings of the campaign for the prevention of infant mortality, workmen's compensation for accidents, old age pensions, housing and town planning, and, eventually, National Health Insurance.

After the First World War

Then came the first world war, the effect of which upon the progress of social medicine was profound. The destruction of young manhood sharpened the need for saving life wherever possible. There was an extension of schemes for the care of mothers and infants and the medical treatment of school children, as well as the establishment of welfare work in industry. As soon as the armistice was signed the Ministry of Health was created. Shortly before the last war there had been a Medical Research Committee under National Health Insurance, but its admirable secretary, Sir Walter Fletcher, made it truly national in its application to the immediate medical necessities of the war, and the Medical Research Council, as it now became, was no merely academic body, but a living and dynamic force for the saving of human life. A concentrated effort was made to combat tuberculosis, and the major local authorities were required to make adequate provision for diagnosis and treatment. Slum clearance schemes were also effected, and later a sweeping measure of Poor Law reform was brought about. In the meantime medical education did not stand still, and the beginnings of two noteworthy movements might be detected at this time, issuing presently in the establishment of the London School of Hygiene and Tropical Medicine and the British Postgraduate Medical School.

What would be the effect on the progress of social medicine of the ordeal through which the world was now passing? He detected a marked difference between the feelings of medical men—and of others—in the last war and in this. In the last war it was the general desire to get back to things as they were, an impatience to resume the old tasks and privileges; but in this war there was everywhere a conviction that great changes were impending. It might be that immediately the war was over an extensive programme of social reform would be introduced, of which social medicine would be an integral part.

Present Gains

Sir Wilson Jameson went on to enumerate some present gains which would surely not be lost in time of peace. Already a co-ordinated hospital scheme existed to meet the needs of the war. Many more hospital appointments had been created, many institutions had been improved out of all recognition—"upgraded," to use the official jargon. The Ministry of Health had itself added 47,000 beds to the total of those already provided by voluntary agencies and local government authorities, and had set up special hospitals for the treatment of head injuries, for neurosurgery, for neuroses, and for rehabilitation. Consultants had been redistributed and their services made available in many places where such provision had formerly been wholly inadequate. Operating theatres had been provided and additional wards built. Laboratory services had been established, for one of which—the Emergency Public Health Laboratory Service—the Government accepted full responsibility. In this work he acknowledged the help of the Harvard Red Cross Medical Unit, which represented by no means the only medical wartime debt which was owing to their professional colleagues in North America.

Again, immunization against diphtheria had become part of the Government public health programme. New methods of attack on tuberculosis had been introduced. The value of miniature radiography must not be overestimated, but it had its use as a means of sorting out the cases which required further examination, and the Minister of Health had undertaken to see that as many sets of apparatus as possible were made available during wartime. A real nutritional policy had been formulated which included collaboration between the Ministries of Health, Food, and Agriculture. There was nothing more praiseworthy than the efforts which had been made in this direction. At last we had obtained as a result of the necessities of the war what had been lacking in the past. A national plan for the collection of hospital morbidity statistics, compiled in accordance with an approved classification, had been set up. Finally, more than ever before, health was in the "news," and prevention had acquired some of the drama of cure.

Encouraging Signs for Peace

There were signs that these gains in time of war would be consolidated. As evidence of the determination to secure much-needed reforms Sir Wilson Jameson mentioned the recent statement of Government policy in relation to hospitals, which was already being implemented by the initiation of surveys in various parts of the country; the adoption by the Royal Colleges of criteria for the training and status of future consultants; the appointment of an interdepartmental committee on the organization of medical schools and the facilities available for clinical teaching and research; and the appointment by the Royal College of Physicians of two other committees—one dealing with the medical curriculum and the other with social medicine. The college had always regarded medical education as one of its main concerns. Here he paid a tribute to the forward policy of Oxford University in establishing a chair of social medicine and to the Nuffield Provincial Hospitals Trust for its support of the university in this venture. Another piece of evidence was the official measures set on foot for the improvement of the status and conditions of work of nurses.

Then there was the setting up by the British Medical Association of the Medical Planning Commission and the character of its interim report. "Surely we are entitled to read into this report a realization on the part of the medical profession that their continued existence as a series of isolated units is in the interests neither of themselves nor of the public they serve. If private practitioners are to take their proper place the medical profession will have to submit to some agreed measure of reorganization."

He concluded with a reference to the part which must be played by the Fellows of the Royal College in moulding the pattern of post-war social reforms. If they were to play their part they must remember Harvey's exhortation to the Fellows and Members in the terms of the Trust by which he brought this annual oration into being "for the honour of the profession to continue in mutual love and esteem amongst themselves."

THE FATE OF PLASMA PROTEINS IN TRANSFUSION

Whipple and his co-workers,[1] in a series of brilliant investigations covering a period of many years, have shown conclusively that the proteins in the cells consist of a part which is necessary for the life and efficient functioning of the cell and a part which can leave the cell protoplasm without apparently affecting the cell's activity. When for any reason the concentration of the proteins in the plasma is reduced—for example, after haemorrhage—protein leaves the body cells and enters the blood stream. If the amount of protein available in the body cells is adequate, the plasma protein concentration may be restored to its normal value; if the protein available is small, the concentration may reach equilibrium at a value below normal. In this event, restoration to the normal value is effected slowly by a synthesis of new protein by the liver from the products of digestion of proteins in the food.

Beattie,[2] after a study of the effects of haemorrhage in experimental animals, came to the conclusion that movement of protein into the blood stream must take place in substantial amounts within a short time after haemorrhage. In a further paper[3] it was shown that after controlled haemorrhages the rate of addition of plasma proteins to the blood is not parallel to the rate at which fluid enters the blood in order to restore the blood volume to its normal level, and does not depend on the amount of blood withdrawn. Beattie regarded these observations as indicating differences in the amount of protein available in the body cells which could be transferred to the blood stream as plasma protein. It was fortunate that a short time previously Wallace and Sharpey-Schafer[4] had made a series of observations on the effects of haemorrhage on human subjects which demonstrated that exactly similar changes took place in man after haemorrhage. In one subject it was found that an average of 13 g. of plasma protein could enter the blood every hour, over a period of 4 hours. This is probably about the maximum replacement rate, and the general rate is much less. However, it is possible, as Beattie[5] has pointed out, that in the first hour after haemorrhage the rate may be even greater. Mass movements of plasma protein in these amounts are obviously of the greatest importance in the mechanism of recovery after blood loss. Whipple and his colleagues[6] have found that infections may slow down or stop the rise in plasma concentration, and have attributed this effect to the drain on the cellular proteins to provide protein bodies used in the manufacture of antibodies and to replace protein lost in inflammatory exudates. Obviously, then, the state of the "stores" of available protein in the body is of importance in the combating of bacterial infections.

The location of the actual site of the stores of protein which can be mobilized and passed into the blood stream, either to raise its protein concentration or to replace wastage from any cause, is discussed in a paper by Beattie and Collard in our present issue (p. 507). A study of data collected by Sharpey-Schafer and Wallace[7] showed that transfusions of plasma or serum in man could be followed by a rapid removal of fluid from the blood stream, as indicated by a maintenance of the haemoglobin concentration at its pre-haemorrhage level. At the same time there was a parallel removal of protein from the blood: the rate of removal was of the order of 4 to 8 g. per minute. As at the same time there was no indication of a rise in the rate of protein breakdown, it may be presumed that the protein leaving the blood entered the protein "stores." Beattie and Collard show that repeated transfusions of plasma into animals were followed, after considerable quantities had been transfused, by a permanent rise in plasma protein concentration. These findings they interpret as indicating that the cells of the protein "stores" could hold no more protein. The amount of protein which can be removed from the blood in man and animals after plasma transfusions is so great that it seems unlikely that the liver alone can be the storehouse. Beattie and Collard, in the same paper, show that hepatectomized animals can store protein and mobilize protein into the blood stream Consequently the mechanism of protein storage may involve the body cells generally.

These observations are of great practical importance. They demonstrate clearly that the reinforcement of the body's protein reserves may be as important a use for plasma transfusions as their employment to increase blood volume after haemorrhage. The making good of protein losses caused by tissue damage, exudate production, and the formation of antibodies can be effected rapidly from the reserve proteins in the cells, and only much less rapidly by the formation of new protein from the food. A successful defence against bacterial invasion needs ample protein reserves. Apart from these acute conditions, there are many more chronic ones which can be benefited by amplifying the reserve proteins. Once inside cells, the reserve proteins can be used not only to raise plasma protein concentration but also to assist in haemoglobin formation and to provide protein needed to replace normal tissue wastage. The ebb or flow of protein between the cells and the plasma under different conditions emphasizes Whipple's concept that the body proteins are in a state of dynamic equilibrium, the level of which is determined essentially by the state of the protein stores.

CONTROL OF MALARIA IN PALESTINE

Palestine in the last war was the seat of important military operations. It has assumed considerable importance in the present war. Our experiences in 1918 showed it to be a distinctly malarious country, and there seems some ground for believing that malaria might well have led to a less successful issue of the campaign than was fortunately the case. Since then there have been many happenings in Palestine, and many changes. A report of some 40 folio pages, entitled "A Review of the Control of Malaria in Palestine (1918-1941)," recently issued by the Department of Health is, in view of these facts, very opportune. After a brief introduction it gives concisely the salient facts about the population, social and economic conditions, and the physiographical and meteorological features of the country. This is followed by a section on "the anopheles carrier and its habits" and one on "endemicity." In the concluding half or so of the report the control measures that have been undertaken, and their results, are dealt with. Altogether 9 species of anopheles have been recorded in Palestine, of which *A. bifurcatus* (*A. claviger*), from its habit of breeding in cisterns and wells and its close domestic association with man, is outstandingly the most dangerous carrier species, more especially in the towns. In the rural areas *A. elutus*, *A. sergenti*, and *A. superpictus* are all dangerous, as experience has shown them to be wherever they are found. Perhaps the most noticeable feature in respect to species is that *A. maculipennis*, which assumed such importance in Macedonia in the last war, does not occur. Palestine, as a matter of fact, lies just south of the great faunal frontier which in its own sphere, like a political frontier, rules the distribution of species. Malaria is almost everywhere endemic in Palestine, though not as a rule hyperendemic. Epidemic manifestations occur from June to September and from August to September, the former due chiefly to an increase in *vivax* infections and the latter to an increase in *falciparum* malaria. Not the least interesting part of the report is that referring to malaria in relation to our troops in the last war. Whilst stationary on the Auja River line, where antimalarial operations were actively carried out, malaria was not excessively prevalent, but with the advance in September into new country it became a serious menace. How far relative escape from malaria whilst the troops were stationary was due to the operations or to the season not being sufficiently advanced is perhaps uncertain, but there is no question that at the height of the season in October malaria was of tremendous importance both to our troops and to the enemy. The report mentions that German sources give 60% as the incidence of malaria among German and Austrian troops in spite of prophylactic quinine.

[7] *Lancet*, 1942, **1**, 699.

The Department of Health began to function seriously from 1920 onwards, attention being at first given chiefly to the towns. By 1922 the rural scheme was in full operation. The inspection of areas and the preparation of schemes based on this were an important activity; 15,430 such inspections were made in 1920, 12,429 in 1921, and 13,219 in 1922. By 1923 so much improvement in the general incidence of malaria had taken place that it was found possible to discontinue the free distribution of drugs except in schools. From 1924 onwards intimate and detailed attention to malaria prevention has been the rule in every town and large village. Reclamation schemes, drainage, dusting with Paris green, visitation of schools, arrangements for the supply of quinine, and other methods have been among those most widely employed. The results as shown by general experience and statistics are extremely satisfactory. The percentage of malaria to total treated in the dispensaries fell from 7.2 in urban areas and 3.2 in rural areas in 1922 to a percentage never higher since the last-mentioned date than 0.7. The spleen rate in the children of both urban and rural areas has likewise fallen. Compared with 1919, the figures in this respect are very striking—e.g., in 1919 the spleen rates for Jerusalem, Safad, Haifa, and Jaffa were respectively 44.3, 68.7, 39.0, and 16.6; in 1940 they were 1.6, 1.0, 0.9, and 0. Not only are these operations carried out by the Health Department during two decades highly satisfactory as having achieved great improvement in both urban and rural areas, but the knowledge and experience so gained of the local conditions in relation to malaria and its prevention should be invaluable to the military authorities in this region. Five excellent maps accompany the report.

VITAMIN C AND RESISTANCE TO INFECTION

Much has been written on the role of vitamins in infection, but critical observations on a large enough scale among human communities are relatively few. Glasebrook and Scott Thomson[1] have now reported the results of a careful study of the effects of the administration of vitamin C on the general health and resistance to infection of boys living in their training school. Though published in the third year of the war, the work was done in the peaceful days of 1938. The institution was a large one, and the distribution of food to its population of 1,500 youths aged from 15 to 20 years was badly managed. Often 8 hours elapsed between the time the food was cooked and its arrival on the dining tables. In the meantime it was kept hot in electric ovens. Analysis showed that the total daily intake of vitamin C of each boy was not more than 10 to 15 mg. Urinary saturation tests showed that the vitamin C depletion of the boys was serious. When some 200 mg. of crystalline vitamin C was given daily to groups of boys the urinary output rose only very slowly, and saturation levels were not reached until after 15–23 days. Thereafter the administration of 50 mg. daily maintained excretion at a level indicative of optimal intake. The training school was divided for administrative purposes into divisions, and youths of each division worked as a unit and occupied certain tables in the dining hall. Observations on the relation of vitamin C to resistance to infection were made by supplying pure vitamin C over a period of several months to one or more divisions. The most common infective conditions in the establishment were coryza and "tonsillitis"; the latter term is used by Glasebrook and Scott Thomson as an index of haemolytic streptococcal disease of the nose and throat and covers tonsillitis, sore throat, otitis media, pharyngitis, and cervical adenitis. Of the 335 boys who received vitamin C 21.2% developed common colds and 8.5% had "tonsillitis." Similar figures, 26% and 8.6% respectively, were observed for the 1,100 youths serving as controls. It was thus obvious that vitamin C had no effect on the incidence of either infection Glasebrook and Scott Thomson then analysed the duration of illnesses in boys admitted to sick-quarters, where the period of treatment was completely outside their control. Over six months the average number of days spent in the sick-room due to infective conditions was 2.5 for a boy in the vitamin-C-treated division and 4.98 for a control boy. When the illnesses were differentiated it appeared that the administration of vitamin C had not shortened the duration of the common cold, which lasted on the average 6.3 days in the vitamin-C group and 6.4 days in the untreated youths. The effect on "tonsillitis" was, however, quite dramatic, as the average stay in hospital due to this disease dropped from 16.7 to 10.0 days as a result of administration of vitamin C, and the effect was statistically significant. It is, however, in the analysis of the more serious illnesses that the difference between the two groups was most striking. There were 17 cases of pneumonia and 16 of acute rheumatism among the 1,100 controls, but no case of either disease among the 335 treated youths. These findings again proved of definite statistical significance.

One could hardly ask for a clearer demonstration of the practical importance of an adequate supply of vitamin C; moreover, the findings of Glasebrook and Scott Thomson are confirmed by the results of the wartime mass administration in Germany of vitamin C to children and adolescents,[2] where the treatment seems to have reduced the incidence and severity of "respiratory infections." Compared with such clear-cut results in the field, laboratory work is less conclusive. Fuller, Roberts, Ralli, and Francis[3] have tried to correlate certain immunological reactions in man with the level of vitamin C and of vitamin A in the diet, but found that the capacity of the nasal secretions to inactivate influenza virus, the titre in blood serum of neutralizing antibodies for influenza virus, the activity of lysozyme in the nasal secretions, the titre of complement in blood serum, and the phagocytic activity for pneumococci of polymorphonuclear neutrophilic leucocytes in whole heparinized blood were not affected by wide changes in the intake of vitamin A or C accompanied by wide fluctuations in plasma levels of these vitamins. Two of their subjects were rendered severely deficient in vitamin C without influence on the immunological phenomena. Such negative findings will doubtless stimulate further research. In the meanwhile war conditions offer both incentive and opportunity for the study of the more practical aspects of the relation of vitamins to infection. There are welcome signs that medical men in the Forces and among the civilian population are giving this urgent matter the attention it deserves.

RAT-BITE FEVER

Though cases of so-called rat-bite fever are continually reported from all quarters of the globe, few have come to light in this country. The last two clinically typical cases described in England followed cat-bites, and in only one instance was an agent, *Spirillum minus*, isolated. Most workers have accepted *Sp. minus* as the aetiological agent in this disease since its isolation by Futaki *et al.*[4] in 1916. They described their micro-organism as a spirochaete, but because of its rigid body and terminal flagella Robertson[5] suggested its inclusion under the spirilla. Many unexplained clinically typical spirillum-negative cases have, however, been described from Japan and other countries. It now seems possible that these have been caused by infection with *Streptobacillus moniliformis*, which has been occasionally isolated in the past from various human illnesses, but until recently has not been seriously considered as a cause of rat-bite fever. In 1933 Strangeways[6] found that *Str. moniliformis* was apparently a normal inhabitant of the nasopharynx in 50% of the laboratory rats which she examined and was also present in four wild rats. This is in striking contrast to the unsuccessful attempts to demonstrate the spirillum in the mouths of rats. *Str. moniliformis* does not grow readily on ordinary laboratory bacteriological media, but grows well on the special solid and liquid media which have been devised for its culture. When possible cases have turned up in the past the usual procedure has been to inject the patient's blood, a lymph gland from the inflamed region, or a piece of the excised wound into guinea-pigs or mice shown not to be harbouring any spiral micro-organisms. Recently Brown and Nunemaker,[7] in a review of the literature and cases occurring in the U.S.A. from 1916 to 1940, found that comparatively few cases of proved spirillar aetiology have occurred. They point out that in every case both *Sp. minus* and *Str. moniliformis* should be sought for. With the use of the new special media for the latter it is interesting to note that of 9 recorded cases which occurred in the U.S.A. in 1939-40 an alleged aetiological agent was isolated in 5: *Str. moniliformis* four times and *Sp. minus* once. They themselves have investigated 8 cases, from 3 of which they isolated *Str. moniliformis*, and in the other 5 the patient's serum agglutinated the organism to an abnormally high titre. Larson[8] has also recently described 3 cases in the U.S.A., from one of which *Sp. minus* was obtained by animal inoculation; *Str. moniliformis* was isolated in a second, and was agglutinated to a high titre by the serum of the third case. None of these investigators has ever isolated both organisms from the same case. In both types of infection the main clinical features are the same. The wound at the site of the bite usually heals without any signs of local inflammation, but after about a week or two induration without suppuration occurs. Fever of a relapsing type develops, along with regional adenitis and lymphangitis. The remission of the fever is usually accompanied by decrease in the severity of the inflammation. A rash of some kind has been described in all the streptobacillus cases and many of those of sodoku. Both types usually show a leucocytosis. Brown and Nunemaker found that the most striking difference between the two types of illness was the high incidence of joint involvement in the streptobacillus cases. However, when Hershfield *et al.*[9] inoculated a large group of patients with *Sp. minus* as a method of treatment, 25% developed arthritis. Sera of a moderately high percentage of both types give a positive test for syphilis. The response to treatment with one of the antisyphilitic arsenicals is usually dramatic and complete in spirillar cases, but has not been so well marked in those caused by the streptobacillus. Recent successful chemotherapy with gold salts in the experimental disease of rats and mice with the streptobacillus and the related pleuropneumonia group of organisms suggests that this is probably a more suitable treatment for human cases of rat-bite fever of this type. Though few cases are likely to be seen in this country it is one more diagnosis to be considered in cases of so-called "P.U.O." with a rash and arthritis. Cases have been reported after bites by cats, ferrets, weasels, and ground-squirrels, dog contacts, cat scratches, and trauma; in one of the last probable cases described in England the patient had no knowledge of any such cause—but his barn was overrun with rats. This list suggests ample scope for possible infection of the large male population in the field in Great Britain.

THE CATARACT OPERATION

Cataract extraction has undergone steady and almost imperceptible changes during the last 20 years. Preliminary iridectomy, which some of the older surgeons used as a routine, is now performed infrequently and only in specially selected cases. Vitreous loss, which was the bugbear of the operation, is now a rarity in uncomplicated cases. This has been achieved largely by the introduction of blocking of the facial nerve at some point or other on its course to overcome squeezing of the eyelids on the part of the patient. Some surgeons use retrobulbar anaesthesia either by itself or with facial blocking, though most avoid this form of anaesthesia because of the lowering in tension it produces, sometimes making extraction of the lens a matter of some difficulty. With improved technique has come a revival of interest in the perennial problem of intracapsular extraction, and an increasing number of operators are resorting to this. One of the main objections to intracapsular extraction from the day it was first mooted about 70 years ago has been the greater tendency to loss of vitreous, and most operators have preferred a larger percentage of satisfactory results to a smaller percentage of brilliant results. With present-day anaesthesia the danger of vitreous loss is appreciably less, and the objections which were previously valid may no longer hold, and it must be recorded as a fact that, whereas before intracapsular extraction was done only exceptionally by operators with special facilities, at the present moment its use is fairly widespread. An interesting contribution to this unsettled controversy comes from M. Klein[1] in an extensive survey of cataract extractions performed by the intracapsular method. The complications recorded are not formidable and compare favourably with results obtained by more standard methods. What is of particular significance in Klein's paper is the challenging suggestion that the vitreous loss is an overrated danger to the eye. The accepted teaching, which is well grounded, that vitreous loss carries with it a possibility of slow infection and retinal detachment is not supported by Klein's careful studies. It is possible that the apparent contradiction between the results reported by him and the accepted teaching reflects the change that has taken place in the operation and its complications. With the older methods of anaesthesia vitreous loss was generally on a formidable scale, and with the present methods this does not often happen. Slight vitreous loss, as Klein rightly insists, is a different entity from massive vitreous loss. This is perhaps the key to the paradox.

TOXICITY OF MERCURIAL DIURETICS

Recent reports of a number of sudden deaths in America following the administration of mercurial diuretics have prompted further investigation and a review of the subject. De Graaf and Nadler,[2] from a study of the literature, concluded that excessive diuresis may sometimes lead to dehydration and chloride loss sufficient to cause restlessness and confusion. A rapid diuresis is unsafe in a patient being given full doses of digitalis, as it may bring on the typical signs and symptoms of digitalis poisoning through mobilization of the drug from the tissue fluids. The toxic reactions most closely related to mercury itself are the disturbances of kidney and gut. On the gastro-intestinal tract the effect is characteristically stomatitis, salivation, and haemorrhagic colitis; but the use of theophylline-mercury derivatives may be expected to lessen the risk of mercurial poisoning owing to the more rapid excretion of the drug. The main changes in the kidneys comprise degeneration of the tubular epithelium, manifesting itself by the appearance of hyaline and granular casts, albumin, and white and red cells in the urine. This is presumably only an extension of the renal irritation responsible for mercurial diuresis, and so the presence of kidney disease is a contra-indication to the use of mercurial diuretics, though such complications are comparatively rare. Chills, fevers, and reactions suggestive of anaphylaxis are probably seen no more often than with any other drug, and may sometimes be avoided thenceforward by changing to another of the mercury derivatives. The immediate fatalities so far recorded fall into an entirely different category. Within 2 to 6 minutes of the completion of an intravenous injection of a mercurial diuretic the patient coughs, flushes, and collapses; on examination the pulse is imperceptible. On some occasions[3] [4] there is clinical evidence of a disordered action of the heart, with forceful irregular ventricular beats. This is comparable to the effect of injecting an excessive dose of the mercurial diuretics into healthy dogs[3] or cats,[5] in which electrocardiograms and direct observation show depression of the T wave and extra-systoles, followed by ventricular fibrillation and death. Acute fatalities have been recorded in sufferers from congestive heart failure[4] and other disorders of the heart, as well as in kidney disease. This is only to be expected from the rapidity of death after intravenous injection of a fatal dose, though De Graaf and Lehman[5] suggest that theophylline may modify the acute toxicity of some of the mercurials by hastening their excretion by the kidneys. These workers have also shown that "esidrone" is much more toxic than the other mercurials for an equivalent weight of mercury. In a small number of fatal cases there were premonitory symptoms during a previous injection, such as a transient rash resembling measles, dyspnoea, and cyanosis.

Due attention should be paid to such warnings. But it is necessary to correct the ominous impression that this account may have given of the mercurial diuretics. The number of fatalities so far recorded is very small compared with the large scale on which such drugs are used. Provided reasonable precautions are taken and administration is stopped when untoward reactions occur, there is no reason to restrict their use in suitable cases.

WORK FOR THE BLIND IN WARTIME

The blind community of England and Wales numbers 74,324, of whom 1,626 are under the age of 16. A fine example of British resilience under adverse conditions is given by the wartime work of the National Institute for the Blind as told in its annual report.[1] Far from accepting a purely defensive rôle on the outbreak of hostilities, the Institute moved into new fields of activity and was soon ready to deal with any war-blinded casualty that might occur among civilians. In this service an important part is played by the homes of recovery, where the newly blinded, from any walk of life, are nursed back to emotional health and prepared for the changed life ahead. There the terrifying reactions to sudden loss of sight "fade away in peaceful surroundings and days of interesting work and pleasure." Meanwhile, the normal services continue. Production of embossed literature has been halved by the paper shortage, but there has been a steady flow of short and topical reading matter. Also, to keep its blind operatives employed, the Institute has been preparing the stereo plates of a number of monumental works which will be printed when paper restrictions are at an end. The war has not hindered the massage services, and the section of the report under this heading will be of particular interest to medical readers, as giving proof of what blind masseurs and masseuses can accomplish after training by experts. With regard to employment generally, which is always a difficult problem, it is said that the labour shortage created by the war is "the golden opportunity for blind labour," and a committee has been set up to secure larger use of the blind in "sighted" factories. The latest annual report of St. Dunstan's is a 6-page leaflet issued from the administrative offices, Inner Circle, Regent's Park, N.W.1. It contains an article, "You Have Conquered Blindness," by the Chairman, Sir Ian Fraser, which might well be read aloud to every newly blinded Service man and woman in the very early days of his or her misfortune.

The Robert Jones Memorial Lecture, on "Congenital Dislocation of the Hip-joint," will be given by Prof. Harry Platt at the Royal College of Surgeons of England, Lincoln's Inn Fields, W.C., on Wednesday next, November 4, at 3.15 p.m.

MEDICAL ASPECTS OF HEAD INJURY

BY

W. RITCHIE RUSSELL, M.D., F.R.C.P.Ed., M.R.C.P.

Temporary Major, R.A.M.C.

The title of this paper is inappropriate, for there are no exclusively medical aspects of head injury. Surgeons, medical neurologists, and psychiatrists have all contributed to our knowledge of the subject, while experience of working in a hospital for head injuries makes it evident that those who wish to treat these injuries should be familiar with all three aspects of the condition, whether they be surgeons, physicians, or psychiatrists. In this short article I shall refer to elementary aspects of head injury which will be of practical help to those who treat these cases and to those who as yet have made no special study of the subject.

Those who have witnessed a severe closed head injury can readily appreciate the popular alarm which is prompted by this form of trauma. The sickening thud as the head strikes on a hard surface is followed by a physical state which is nearly related to death and which must necessarily suggest serious injury to the brain. Moreover, in medical practice we are all familiar with cases of the chronic post-concussional syndrome, which appears to cause marked disability for many years. These patients are unhappy invalids and are often resistant to treatment. Experience of cases such as these causes both the medical officer and the layman to take a pessimistic view with regard to prognosis in cases of head injury.

It is important, therefore, that there should be a clear understanding regarding the incidence of symptoms following head injury. Figures for Service cases are not yet available, but in the civilian closed injuries from road accidents, falls, etc., the following figures indicate that the incidence of post-concussional symptoms is much lower than is generally realized and that the duration of disability is surprisingly short.

In Table I 200 consecutive patients, admitted to the Royal Infirmary, Edinburgh, were interviewed 18 months after their head injury. They were asked about their symptoms since leaving hospital (including slight ones, such as nervousness, occasional headache, or giddiness); and the duration of any symptoms referable to the injury was noted.

Table I.—*Duration of Symptoms (Severe or Slight) after Head Injury in 200 Unselected Cases*

Duration of Symptoms	No. of Cases
Under 2 months	80
2–6 months	11
6–18 months	30
Over 18 months	79

It will be seen from the table that in 40% of cases there were no symptoms after 2 months, but in an equal number symptoms (often slight) persisted for over 18 months.

Table II.—*Duration of Unfitness for Full Work in 100 Working Men and Women under the Age of 50—Compensation Cases excluded.*

Interval after Injury of Successful Return to Full Work	No. of Cases
Under 2 months	61
2–6 months	26
6–18 months	7
Unfit after 18 months	6

The severity of the post-concussional symptoms in the average case of the working man or woman is indicated by Table II, where the period off full work (following the injury) is recorded.

It should be noted that 87% had returned to *full* work within 6 months of the injury. Compensation cases and patients over 50 years of age were excluded.

Table III compares the period off work with the severity of the injury (as indicated by the duration of post-traumatic amnesia). This group consists of 92 working men and women under the age of 40.

Table III.—*Duration of Unfitness for Full Work compared with Duration of Post-traumatic Amnesia*

Interval after Injury of Successful Return to Full Work	Duration of Post-traumatic Amnesia		
	1 hour	1–72 hours	Over 72 hours
Under 2 months	30	25	4
2–6 months	1	8	13
6–18 months	1	3	3
Unfit after 18 months	0	1	3
Totals ..	32	37	23

This table gives a striking indication of the quick return to work of young people, even after severe injuries.

Table IV.—*Duration of Unfitness for Full Work compared with the Presence of Fracture of the Skull*

Interval after Injury of Successful Return to Full Work	Fractured Skull	No Fracture
Under 2 months	11	31
2–6 months	17	10
6–18 months	6	2
Over 18 months	6	7
Totals	40	50

In Table IV the rates of return to work in those with and without a fracture of the skull are compared: it demonstrates clearly that the duration of disability bears little relation to the presence of fracture.

These tables indicate that, though head injury may cause permanent damage to the brain and, in some, symptoms of varying degree, these disabilities should only rarely prevent resumption of manual work within 2 to 6 months of the injury. Reduction of efficiency is common after severe injuries, but is rarely sufficient to cause much disability. It is obvious, therefore, that far from being pessimistic regarding the prognosis after head injury, we can usually be confidently optimistic. The importance of expressing this optimism during treatment will be stressed.

I shall not here refer to the treatment of the acute stage. The recognition of complications in the early days, such as cerebral compression by haemorrhage, depends chiefly on the study of the temperature, pulse, blood pressure, and respiration, the degree of consciousness, and the development of abnormal neurological signs such as hemiplegia.

Meningitis is one of the most dreaded complications, but is often prevented by modern surgical treatment of wounds and by chemotherapy. All cases in which there is a persistent discharge of cerebrospinal fluid from the nose, however slight it may be, should be transferred promptly to a neurosurgeon so that he may close the meningeal fistula and thus prevent the dangerous complication of meningitis. The earliest signs of meningitis are a delayed rise of temperature, neck rigidity, and increased clouding of consciousness. An early increase in the white cell count in the cerebrospinal fluid provides the first evidence that this complication is developing. When the fluid is blood-stained both red and white cells must be counted to enable this pleocytosis to be recognized. Blood contamination of the cerebrospinal fluid will account for only one or two white cells per thousand red blood cells.

Complications which Often Cause Unnecessary Alarm

To those who are unfamiliar with the varied clinical course that may follow head injury it may be helpful to consider certain complications which sometimes cause needless anxiety and unnecessary operation.

An *epileptic fit* occurring during the first two or three weeks, whether local or general, does not indicate any serious complication unless it is followed by clinical evidence of further damage to the brain, such as hemiplegia; nor are these cases much more liable to develop traumatic epilepsy after recovery.

Delayed facial paralysis is common when there has been bleeding from the ear. The paralysis, which is usually complete, comes on within two or three days of the injury, and is probably due to some chemical change in blood clot in the facial canal. The paralysis should be treated as in Bell's palsy; recovery occurs usually in a few weeks, but sometimes by regeneration after several months (see below).

Neck rigidity is often thought to be due to meningitis, but is usually due to subarachnoid haemorrhage. Both these complications, however, may coexist; they can then only be clearly distinguished by counting the red and white cells in the cerebrospinal fluid as described above. Injuries to the cervical vertebrae are referred to later.

Bradycardia.—Abnormal slowing of the pulse often develops 2 to 4 days after severe closed head injury, and may continue for 2 weeks or more. During this period a pulse rate of 40 to 50 a minute is not uncommon. This complication need cause no anxiety, provided there is no associated deepening coma or other neurological evidence of progressive cerebral compression.

Papilloedema.—Contrary to much former teaching, increased intracranial pressure is seldom a dangerous complication in uncomplicated head injury. Papilloedema is not often present, but it occasionally develops to a slight degree 1 to 3 weeks after severe closed injury. This complication may occur without there being intracranial clot or other similar complication; apart from delaying convalescence, it is in itself of little importance.

Prolonged confusion or delirium is common after severe closed head injury and may continue for several weeks. This is not usually due to any vascular complication, such as cerebral oedema or compression by clot, but is apparently dependent on the nature of the original brain commotion. Careful nursing, with forced food and fluids if necessary, is the most important part of the treatment of these cases. Remarkably good mental recovery ultimately occurs in many severe cases, and a bad prognosis in this respect should not be given during the period of confusion. Sedatives should be avoided so far as is possible, as these delay mental recovery. Physical restraint should be minimal; after the early days a bath, sitting in a chair, or a walk along the ward will do no harm and often relieves restlessness.

Associated Injuries.—These may cause confusion in diagnosis and are easily overlooked. Injury to the cervical vertebrae sometimes results in weakness of the arms or legs which may be mistaken for cerebral paralysis. This injury causes a painful stiffness of the neck, movements of rotation being specially affected—unlike the stiffness due to subarachnoid haemorrhage or meningitis, which affects forward flexion of the head. Tearing of the brachial plexus may be a cause of paralysis, as also may fractures of the extremities or dislocation of joints; such paralysis is sometimes erroneously thought to be due to the brain injury.

Examination during Recovery—Repeated examination during recovery should be made with a view to determining whether mental and physical functions are being restored. Regarding the intellectual functions, the unskilled observer is often misled by the patient's statement that he has quite recovered and by his apparently normal speech, when in fact he is still confused and disorientated. Disorientation for time and place is common, the patient often thinking that he is living in a period several years earlier. For example, a Polish airman seen recently after a crash was convinced that he was in Poland; he said the year was 1936, and that he had crashed in a German sports plane: he discussed intelligently the prospects of future war with Germany. As the intellectual functions recover, this long retrograde amnesia usually shrinks to a period of less than half an hour before the accident. Questions and discussion regarding recent world news will give a good idea regarding the state of intellectual recovery. Simple memory and calculation tests may also be used. When there is evidence of dysphasia this requires careful investigation.

Physical Examination

Physical neurological examination is necessary to detect damage to cranial nerves and brain. *Anosmia* is common in severe fractures of the anterior fossa and in occipital injuries (by contre-coup). This disability is usually permanent, and of course renders the soldier unable to detect many poisonous gases, including coal-gas. Damage to the *optic nerves* or *chiasma* is also usually permanent, and is recognized by loss of vision, by defects in the visual fields, and by pallor of the optic disks, which appears in about two weeks. Most *oculomotor palsies*, even when complete, recover well after a few weeks; but damage to the superior oblique muscle or its nerve may result in permanent diplopia. Ophthalmologists have recently discovered how to cure this disabling diplopia by operation.

Damage to the branches of the *trigeminal nerve* produces areas of anaesthesia over the face. This usually causes no disability, but sometimes leads to a troublesome form of neuralgia, which may be difficult to relieve even by operation on the nerve.

Peripheral *facial paralysis* associated with fracture of the base of the middle fossa may be immediate or delayed, as referred to above. Many of these cases recover completely in less than two months. Others recover gradually by regeneration over a period of up to 18 months; but this recovery may be incomplete, as in comparable cases of Bell's palsy. Recovery by a process of regeneration is recognized by faulty voluntary control of the facial muscles—attempts to move the upper facial muscles causing movements round the mouth, and vice versa. Complete failure of recovery after traumatic facial paralysis is extremely rare.

Fracture through the base of the middle fossa with haemorrhage into the middle-ear causes slight *middle-ear deafness* but no permanent disability. *Inner-ear deafness* is usually permanent, and occasionally becomes progressively worse. *Tinnitus*, often associated with inner-ear deafness, may be permanent, causing mental discomfort, which varies according to the loudness of the tinnitus and the patient's sensitivity to this irritating symptom; in many cases it occasions no disability and requires no treatment. *True vertigo* may also be troublesome.

Gross injury to the cerebral hemispheres, causing, in the acute stage, hemiplegia, astereognosis, homonymous hemianopia, or aphasia, often recovers well. Most of the possible recovery occurs within 3 months, and thereafter slight improvement continues for as long as 2 years.

Treatment during Recovery

In most cases of closed injury in young subjects a good recovery can be confidently predicted if the patient survives the first 24 hours. It is noteworthy, therefore, that within a short period of admission to hospital the atmosphere around the patient should change from one of anxious care to that of cheerful optimism. The second stage should be reached, if possible, before recovery of full consciousness. The patient's mental reaction to recovery of consciousness in bed, surrounded by dim lights and shadowy figures, with a splitting headache, confused thoughts, and complete amnesia for the reason of it all, may be almost catastrophic, and frequently sows the seed of a future anxiety neurosis. Medical and nursing personnel often aggravate this reaction by talking to him of severe concussion, fracture of the base, probable long incapacity, and possible after-effects. These sadistic activities must be rigorously suppressed. Nurses and relatives must be clearly told, whenever possible, that an excellent recovery is expected within a reasonable period. The patient's fears regarding his amnesia for the accident and its possible effects are relieved by simple explanation, and the expectation of good recovery is impressed on him. It is obvious that in cases with destructive lesions of the brain causing perhaps hemiplegia or aphasia the prognosis must be more guarded. It is important to remember, especially if there is a personal or family history of nervous instability, that head injury is one of the most common nuclei around which a patient will weave neurotic symptoms or exaggerations of slight bodily sensations. Careful convalescence and rehabilitation under intelligent and interested medical supervision have proved to be of the greatest value in ensuring the quickest and most complete recovery.

The period of rest in bed is the first point to consider. There are commonly applied rules for cases of fracture of the skull that are better discarded, as the radiograph gives little indication of the degree of brain damage. There is no need to keep a man who feels perfectly well after head injury lying in bed for 3 to 4 weeks just because the radiograph shows a slight fracture. His symptoms and clinical state provide the best basis on which to judge of the necessary period of rest.

In the average case the patient should be kept strictly in bed for about 7 days after full return of consciousness, or 5 days after relief from headache. Thereafter, allow him up for half to one hour more each day, according to the severity of the injury; slow down this process, or reverse it with a whole day in bed, if symptoms recur. After he has been up all day with little or no symptoms, start graduated physical exercises of a degree which causes little headache or dizziness, and work up gradually to the full exercises of the fit soldier. While little attention should be paid to slight headache or dizziness, medical supervision should be continued, as some patients require slower convalescence than others and some should not be expected to do the heaviest forms of P.T. in the early months following the injury. Some patients will require to be kept back, while others need encouragement. Under ideal conditions the same medical officer will supervise the case till the patient is fit to return to duty.

Prognosis

The prognosis and duration of treatment in all cases, whether acute or chronic, depend on three main factors: first, the severity of the injury, as indicated by the duration of amnesia and clinical evidence of brain damage; secondly, the age of the patient—if under 30 recovery is usually very good, it is slower between 30 and 40, and at over 40 it is often definitely slower and less complete; finally—and often the most important, as Symonds has stressed—the patient's previous personality and intelligence. The man with a good brain and personality recovers best; while the neurotic, the psychopathic personality, and the mentally dull often recover slowly and with many setbacks. An essential part of the investigation is therefore an inquiry into the soldier's previous intelligence, work and service record, tendency to neurosis, and family history.

An *approximate time-table* for closed head injuries with no complications or evidence of gross brain damage is as follows, severity of injury being roughly estimated by the duration of post-traumatic amnesia:

Slight cases—amnesia less than 2 hours—should be fit for full duty, category A, in 3 to 6 weeks. Delay for 2 to 4 weeks if fractures of skull are extensive or if symptoms are severe.

Moderate cases—amnesia of 2 to 48 hours—should be fit for full duty, category A or B, in 1 to 4 months, according to severity of post-concussional symptoms.

Severe cases—amnesia of over 2 days—should be fit for duty in category A, B, or C in 3 to 6 months.

This programme suits the average case of closed head injury, but a small proportion from all three groups will be permanently unfit for any form of service. The chief causes of permanent unfitness are:

1. *Physical destruction of brain tissue or of cranial nerves*, causing, for example, hemiplegia or hemianopia.

2. *Intellectual and Memory Impairment.*—This rarely occurs in young patients to an incapacitating degree, but is commonly severe in those over the age of 40 who have had very serious injuries. It produces considerable disability in N.C.O.s, especially if their previous intelligence was below the average. They are forgetful, are easily flustered, and quickly break down with anxiety, depression, and psychogenic headache. A slight degree of intellectual impairment often causes no noticeable disability to the private soldier, unless his previous intelligence was low. Transfer to the Pioneer Corps may sometimes be a satisfactory method of disposal. Intellectual impairment may result in a striking change of personality with behaviour disorder. This occurs most frequently in children and in adults of unstable personality. Soldiers of this type usually prove to be unfit for further service.

3. *Traumatic epilepsy* develops in about 3% of closed injuries, but in a much larger proportion after penetrating gunshot wounds. The fits usually develop 3 to 18 months after the injury; but the onset may be much later, especially after penetrating wounds.

4. *Organic Complications during Convalescence.*—Though the great majority of cases of head injury improve steadily and satisfactorily during convalescence, it must be remembered that chronic subdural and chronic extradural haemorrhage, delayed cerebral haemorrhage, arteriovenous aneurysm, cerebral abscess, and meningitis are occasional delayed complications. Abnormal drowsiness and other evidences of impaired cerebral function are important early signs of those complications, and call urgently for full investigation of the case, as prompt surgical treatment may be required.

5. *The Chronic Post-concussional Syndrome.*—This syndrome consists of symptoms such as headache, dizziness, nervousness, loss of concentration, and anxiety, which persist indefinitely after a head injury that is often slight. The headache is in many cases described as "terrible," is frequently continuous, and is not relieved by headache powders. The dizziness is seldom due to true vertigo, but is usually a feeling of light-headedness during which "things go black" and the patient requires to steady himself or to sit down for a few seconds to get relief. On careful analysis of the chronic cases it generally becomes apparent that the physical symptoms are slight but are grossly aggravated and exaggerated by psychological factors, of which, as a rule, anxiety is the most prominent—the patient having become "head-conscious," in the same way that the dyspeptic may become "stomach-conscious."

This troublesome syndrome can usually be prevented if convalescence and rehabilitation are organized and supervised as described above. The point to be emphasized is that though headache, dizziness, and nervous symptoms may persist as occasional post-concussional complaints for many months or even years, they cause negligible disability in the stable young soldier or airman.

The mental attitude of some Service patients to their injury corresponds to that observed in civilian compensation cases, and consequently the duration of disability is prolonged by the aggravating effect of anxiety neurosis or sometimes by deliberate exaggeration. In soldiers a fear of future head injury is a common cause for anxiety, and may develop, for example, when doing guard duties at night.

It is important to realize that graduated physical re-education will do these chronic cases no harm, and indeed has been proved to be the best treatment for the chronic headache and dizziness: it must, however, be combined with simple psychotherapy.

Psychoneurosis following head injury is more easily prevented than cured, especially when there is an element of malingering; but much can be done by explanation, encouragement, physical re-education, and discipline. For the difficult cases, duties should be chosen which suit individual temperament, interests, and capabilities. A feeling of discontent or a sense of grievance will greatly increase the difficulty of handling these cases.

Conclusion

It should be noted that modern treatment of head injuries aims at returning the soldier to duty sooner than some old traditions would allow. As has been pointed out, this programme is based on a study of the quick rate of recovery in patients of good type in whom there was no compensation or other factor which retarded progress. Experience has fully justified this aim, and has led to a considerable reduction in the period of disability. We have some failures, but even with these it is evident that vigorous methods of physical rehabilitation have at least done no harm.

In an experimental investigation into the effect of plasma transfusion on serum proteins, E. W. Shearburn (*Surg. Gynec. Obstet.*, 1942, **74**, 343) fed dogs with what was essentially a protein-free diet. On this diet the blood protein and blood volume decreased. A single transfusion of plasma calculated to restore the concentration of serum protein to animals proved ineffective, but the hypoproteinaemia was corrected by small plasma transfusions given once or twice daily.

CLOTHES AND FUEL SAVING

BY

Sir LEONARD HILL, LL.D., M.B., F.R.S.

If when France fell and her coal supply ceased our miners had all been kept in the pits and none enlisted, through foresight of future demands of new munition factories, no shortage of fuel would have resulted. The shortage has now come at a time when there is rationing of food, and particularly of fats, which have the highest heat-producing value, and of clothes by means of which body heat is conserved. If no fires are lit and people feel cold they can keep warm by greater activity, some 80% of the energy spent in muscular work appearing as heat. In consequence, however, there will be greater need of food, and if this is not available, loss of body weight. The alternative is to put on more clothes, and this is the most economical plan. Eskimos, Arctic travellers, and airmen keep warm by suitable garments enclosing all the body except the face in wind-proof manner. An Eskimo clad in furs will watch by a seal hole for hours, and even days, when there may be 50 degrees or more of frost and Arctic winds blow. Roman Catholic priests nurtured in Europe live in the far north in like manner with the Eskimos, whose diet of fat fish and seal meat and blubber is of high energy value. The greatest saving of fuel will be made if people will clothe themselves so that the temperature of factories and rooms can be kept at a lower level than usual. For those adequately clothed only enough artificial heat is needed to keep the hands warm enough for doing skilled work. To effect this great saving the clothing ordinarily worn out of doors for travelling can be brought into use, an overcoat, cloak, or raincoat being worn over the underclothes. The factory workers can wear their warmest underclothing under the trousered overalls supplied for their work.

Conservation of Body Heat

The northern Chinese withstand months of rigorous cold weather, using little fuel, by wearing long-sleeved wadded gowns, and wadded trousers bound round the ankles. The thin "undies" and skimpy dresses of women require warm rooms in winter; to save fuel they must be amplified as set out above. It is not the fibre of a garment which protects from heat loss, but the air which—a bad conductor of heat—is entangled in the woven mesh and between the layers of clothing. This air, if kept stationary in the meshes of the garments, becomes warmed up nearly to body temperature. Draught or wind must be prevented from blowing this air away, and replacing it continually by fresh cool air. A given volume of fur contains about 2% of solid and 98% of air, and an animal orientates to wind so as to keep its fur from being disordered. Fur and feathers have very great heat-retaining power combined with lightness and flexibility. The water bird by greasing its feathers keeps the water out. A penguin maintains a body temperature some degrees higher than ours when exposed to blizzards and 50 or more degrees of frost. Sedentary workers can keep warm at their desks, as they do when travelling in a car, by wearing an overcoat, a rug round the knees, and, if needed, a hot-water bottle at the feet. So protected, with no fire and window open, work can be done with improvement in health, as in the case of patients given open-air treatment.

While children taken from city tenements are benefited by exposure to open air and sun, this must not be beyond their power of assimilating food and increasing body heat production. Open-air workers suffer little from so-called "colds." These affections are spread by infection in shut-up artificially heated rooms. In sanatoria it is the nurses, who use such rooms when off duty, and not the patients exposed to open-air conditions, who catch "colds." "Colds" only affect Arctic settlements when ships visit them and bring in infection. It will be far better for health to wear more clothes than to cut down ventilation of factories in order to save fuel.

Protective Value of Fabrics

The heat capacity of water is more than 3,000 times, and its thermal conductivity at least 240 times, that of air. The cooling power of water is thus very great. The effect of cold wind is also great. The heat loss of a naked man in a room at 40° F., with the air moving at a rate of 6¼ ft. per second, was twice as great as when clothed. The cooling power of the environment and the protective effect of clothes can be measured by the katathermometer—a large-bulbed spirit thermometer—which is warmed above 100° F., the time to cool from 100° to 95° F. being then taken with a stop-watch. Three knitted gloves put on the "kata" reduced the cooling power to about one-third of that of the naked instrument when suspended in air. The cooling power of water exerted on the naked "kata" was fourteen times that of air at the same temperature. If a thin rubber glove be put on over a thick woollen glove and the "kata" put in water its cooling is very greatly lessened compared with a naked "kata." The protection becomes considerably less when the under-glove is wet, but is still noteworthy, some air being entangled in the wet glove and evaporative loss impeded by the rubber glove. Wool is the best material to wear when clothes are wet, for it does not cling to the skin owing to its elastic fabric. Otherwise, so far as concerns warmth, it is the weaving and not the nature of the fibre which matters. Smooth-woven linings to coats increase their wind-proofness. Water-proofed garments are also wind-proof. Some years ago on inquiry of the Board of Trade concerning the maintenance of life in shipwrecked people, Argyll Campbell and I carried out tests on the heat loss of man when exposed to wind and splashing of waves, and found that a one-piece suit of water-proofed material, designed for them by Sir Robert Davis, lessened such loss by about one-half—that is, when worn over ordinary clothing.

I drew the attention of the Minister of Transport to this research, with the result that our merchant seamen are now all provided with a two-piece dress, designed by the Ministry, made of light oilskin material, and coloured yellow to be visible to air pilots. The dress packs into its hood and can be always carried in the same way as is a gas-mask. This dress adds greatly to their powers to resist exposure when the sailors, after wrecking of their ships, are in boats or on rafts. Given warmth and enough water to drink, they can survive with little or no food for many days.

Physiological Common Sense in Hot Climates

Black or dark garments are worn in cold climates, because the dark colour absorbs the radiant heat of sun and sky, while white is worn in the Tropics because it reflects much of the rays. The black skin of the negro, absorbing the rays, is excited to transpire water vapour and sweat; the glistening moist skin then reflects the rays. Protected by pigment the negro skin can be thin and heat loss is thus made easy from shaded parts. Convention should not keep white children clothed in the Tropics; they should go nearly naked and tan in the sun. Heatstroke is favoured by tight clothes, crowding, hot ground, high humidity of the air, and little wind. It results when the sweat glands cease to be effective; and can be warded off by a wet sheet placed over the patient and a fan set to blow on this and cause evaporative cooling. To secure efficiency of work in hot surroundings clothes must be mostly discarded, ventilation made adequate, and enough water for drinking supplied to keep up sweating. This is best slightly salted to balance the loss of salt in the sweat. The diet must be a light one so as to reduce heat production in the body.

At a quarterly court of the directors of the Society for Relief of Widows and Orphans of Medical Men, held on Oct. 7, the chairman, Dr. R. A. Young, senior vice-president, reported the death of the president, Mr. V. Warren Low, who had held office for thirteen years, and whose death will be a great loss to the society, as he had always taken the greatest interest in its work and was rarely absent from meetings. One new member was elected, and the audited accounts for the half-year ended June 30 were presented and approved. The receipts amounted to £3,611; the half-yearly grants to widows came to £1,937; and £2,090 had been invested in Defence and Saving Bonds. After being in abeyance for some years it was decided to make a Christmas present of £7 10s. this year to each widow in receipt of grants. Membership of the society is open to any registered medical man who, at the time of his election, is residing within a twenty-mile radius of Charing Cross. Relief is granted only to the widows and orphans of deceased members. Full particulars may be obtained from the Secretary, 11, Chandos Street, W.1.

Reports of Societies

STILLBIRTH AND NEONATAL MORTALITY

At a meeting of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine on Oct. 17, Dame LOUISE McILROY presiding, a discussion took place on "Stillbirth and Neonatal Mortality."

Prof. D. BAIRD (Aberdeen) said that statistical analyses showed great differences in this mortality as between one country and another and between different areas of the same country. In 1936 in England and Wales 25,045 stillbirths and 18,200 neonatal deaths were recorded. It had been long recognized that infant mortality was largely dependent on poverty and low standard of living, and stillbirth and neonatal mortality rates might be similarly influenced. The exact cause of stillbirth was often difficult to determine, especially in domiciliary practice; and even in hospital, with the aid of routine post-mortem examinations, it was not easy. The appendix to the Registrar-General's report for Scotland (1937) classified 37% of stillbirths as of unknown or ill-defined causation, 14% as due to difficult labour, and 13% to foetal abnormalities. The speaker had attempted an analysis of cases in the only maternity hospital in his area, thus obtaining a cross-section of the stillbirth rate in Aberdeen during the period taken. The rate was 36 per 1,000. In 30 cases out of a total of 82 the cause was unknown, in 24 it was difficult labour, and in 9 toxaemia. Among emergency cases admitted to hospital difficult labour naturally entered largely, and, with placenta praevia, accounted for 50% of the cases.

The importance of neonatal mortality was evidenced by the fact that, in Scotland, 50% of the infant death rate related to the first month of life. In Scotland in 1937 the neonatal mortality was 38 per 1,000 births, in the North of England 34, in the South-East of England 24, while in large cities it varied from 43 in Glasgow to 24 in London. The London figure was about the same as for New York and Chicago, whereas Amsterdam had the low figure of 16. Among the booked hospital cases the biggest factor was infection. One of the chief problems was the prevention of prematurity. Many hospitals lacked provision for dealing with premature babies. Maternity hospitals should have special nurseries on the cubicle system for such infants. The incidence of premature labour in booked hospital cases, which represented the working-class community, was about 9%; among the middle and upper classes (in a series of 885 cases) it was 6%, and among booked specialist cases (330)—that is, patients coming in the early months of pregnancy, not because they were ill, but because they wanted to be under specialist care from the beginning—it was 2%. The neonatal mortality in these three groups was respectively 3.3, 1.35, and 0.6%. Stillbirth and neonatal mortality rates, as well as the infantile death rate, were higher in Scotland than in England, but 60 years ago the reverse was the case, and presumably there was no inherent weakness in Scottish offspring. In depressed areas measures to lower the mortality should take the form of better feeding of pregnant women and nursing mothers, intensive teaching of mothercraft during pregnancy, the provision of more antenatal beds for the treatment of complications, better postgraduate training of doctors and nurses, and better training of health visitors.

Paediatric Aspects

Prof. CHARLES MCNEIL (Edinburgh) said that the first month of life formed a bridge-head between obstetrics and paediatrics. He based his remarks on an analysis of 416 cases of stillbirth and, during the same period, 236 neonatal deaths. Post-mortem examinations had been carried out in 540 of these 650 cases. There was found to be a much higher incidence of congenital defects in premature children, so that congenital deformity was somehow linked with prematurity. Asphyxia had a prominent position in causes of death of both premature and immature infants, the anatomical explanation being that the infant's lungs were stiff and difficult to inflate. Paediatrics as a medical service, in contrast to obstetrics, was poorly equipped. There should be a strengthening of paediatric staffs in maternity hospitals. The diet of expectant mothers should also receive more attention. More needed to be learned about the first beginnings of the complicated process called digestion, which after birth was for the baby an entirely new mechanism. Measures should be taken to protect the baby in hospital from the great danger of infection, particularly from gastro-enteritis, which stood out easily first among infections as a cause of death. Every maternity hospital should have a follow-up clinic for its babies, and a much closer supervision of them during the first month of life, whether in hospital or out of it, especially as regards dietetics.

Dr. DOYNE BELL said that the treatment and prevention of immaturity—which he defined as some degree of unsuitability for extra-uterine life, as contrasted with prematurity, which denoted merely a time factor—were highly relevant to the present discussion. He criticized both the recent Toronto investigation which had been mentioned by Prof. Baird and that of the People's League of Health in London. In the former investigation the control series of patients was not strictly comparable with the subjects of the dietetic experiment, and the records of infant deaths were not stated in such a way as to permit of any valid conclusion being drawn. With regard to the latter investigation he gave reasons for thinking that the yardstick was not accurate enough to warrant the significance attached to the figures. An analysis of a series of unselected pregnancies showed that the range of error likely to occur in the estimation of the duration of gestation rendered conclusions based on the concept of prematurity highly unreliable. In spite of loose certification of neonatal deaths, both as to their exact cause and as to their exact age, it was probable that immaturity played an important part in their causation, but there was no reason at present to suppose that the problem of preventing immaturity had been solved. The prevention of neonatal death from immaturity could, however, be assisted by an adequate paediatric service. The maternity hospitals were not at present required by any Act or regulation to provide proper paediatric supervision of newborn infants.

Sir FRANCIS FREMANTLE, M.P., said that the neonatal mortality figures had improved slightly during the last three years, although infant mortality as a whole had risen, but not much, even on the very low figure for 1939. The increase and improvement of ante-natal clinics had taken place on a large scale. At the end of last year there were in England and Wales 1,600 of these under the aegis of local authorities and 260 under that of voluntary associations. The attendances last year were 452,000, and first visits paid by health visitors numbered over half a million. In all the surveys the general finding was that conditions of infant life were much more alarming when associated with poverty. But the economic conditions which created poverty were in some degree the result in present or previous generations of weakness of character or intelligence. It was not merely the social conditions which produced the statistics so much deplored; they were partly due to the fact that many of the people concerned were not able to look after themselves. Merely to improve the housing, necessary as that was, would not bring about the desired results. On the other hand, there were countless instances of people living in slums in the midst of penury who yet, because the mother was scrupulously clean and a good manager, brought up a healthy family. The problem must not just be left to Government provision, national or local, but the people themselves must be taught to use their own powers and intelligence.

The League of Health's Inquiry

Prof. JAMES YOUNG said that the report of the People's League of Health (*British Medical Journal*, July 18, 1942, p. 77) was probably the most comprehensive and best-controlled investigation ever carried out on this subject. It revealed two important results of statistical significance from the standpoint of the present discussion. The incidence of pregnancy toxaemia was about 30% less in women who received additional dietary supplements than in the control women, and toxaemia was known to be one of the chief factors in prematurity, stillbirth, and neonatal death. In the second place, the prematurity rate was about 17% less. The investigation could not be expected to reveal the full effect of the improved nutrition because in the majority of cases the women first entered the experiment at a stage of pregnancy when the major risk of abortion had passed. The food supplements were given in the form of tablets and capsules, the only method by which such a large nutritional experiment was possible, and no doubt it was true that natural foods would be even more effective, so that the results, striking as they were, represented rather the minimal than the maximal influence of good nutrition. He added some up-to-date figures relating to changes in infant birth weights, prematurity rates, and toxaemia rates since the war began. The study had been carried out by Dr. Hargreaves at the British Postgraduate Medical School on "booked" cases during 1937 (1,597 cases), 1938 (1,765), 1940 (954), 1941 (846), and 1942 (662). The average birth weights of full-time children had shown a decline since the pre-war years from 7.3 to 7.1 lb. in primigravidae and from 7.6 to 7.4 lb. in multigravidae. The percentage prematurity rates had declined, though not so consistently, from 19.7 to 14.2 in primigravidae and from 16.7 to 13.6 in multigravidae. The percentage toxaemia rates had shown no consistent change.

Prof. **Baird**, in his reply, said that the appointment of paediatricians to emergency hospitals was desirable, but this would be only a wartime measure, and what he desired to see was appointments of the type recently made in Newcastle, where a doctor had been appointed "Professor of Child Health." He had been interested in Prof. Young's figures. The incidence of toxaemia in primigravidae in Aberdeen in booked cases was 8%, which was very close to the London figure, and he had always understood that there was relatively little toxaemia in maternity cases in London. In a small series of cases in private practice the toxaemia rate was only 3%, or less than half the hospital figure. The percentage prematurity rate in Aberdeen among hospital cases was 23, but in private practice only 8.

Correspondence

What is "Sterile Blood"?

Sir,—Recent contributors to the *Journal* have raised the above question and answered it to their seeming satisfaction, but not without leaving an opening for legitimate criticism. The question as to what constitutes "sterility" is evidently a matter of some perplexity. This is borne out by the report of four experts from the Blood Transfusion Service of the Medical Research Council as published in the *Journal* of March 21, 1942. These workers eventually decided that the ordinary bacteriological tests for the sterility of plasma were of little value, and they discarded them in favour of the naked eye as a check on their plasma storage technique.

Now the experienced bacteriologist may be able to say that cloudiness of plasma or serum means contamination and that clearness argues for probable sterility, but it is a departure from our usual scientific standards to dispense with proof of absolute sterility. It is quite obvious that in dealing with blood the bacteriologist is missing the free use of his autoclave, and that when he speaks of sterile blood he does not mean the same thing as when he refers to a sterile dressing. Everyone knows what is meant by the usual sterile fluids; they have been boiled or otherwise sterilized in order to kill off all forms of life within them. On the other hand, "sterile blood," although free from bacteria, is still a living tissue, but the activities of the living elements in stored blood have so far not had much consideration. There is in fact a widespread belief that the changes which take place in clean stored blood are purely physico-chemical, when as a matter of fact they must include the biological reactions of living things. It becomes necessary therefore to differentiate between those changes which are due to the inherent vital elements in blood and those which are due to contamination. Nor should we forget that the value of blood for many transfusion purposes is greatly diminished by the present storage processes, which aim at suppressing the extraneous forms of life but at the same time destroy the inherent vitality of the blood cells.

This vital aspect of blood was recognized by Crosbie and Scarborough,[1] who, among other criteria of the viability of the white blood corpuscles, described a curious "spinning" of the granules of the cytoplasm. This rapid oscillatory movement stops immediately when the cell is overheated—in short, when living protoplasm enters into its dead state. I have confirmed this observation, but I have gone further and found that, as the white cells break up, these spinning and, as I hold, living bodies can be seen floating free in the blood serum. With suitable technique, such as the use of dark-ground illumination under a high-power objective, it is also possible to demonstrate that there are other highly motile bodies in disintegrating "sterile blood."

We are faced then with the need for a more intensive investigation of the biological phenomena of stored blood which has been pronounced "sterile." It is clear also that the word "sterile" is not a suitable term in this connexion, because the state of sterility is inconsistent with the presence of vital elements in stored blood.—I am, etc.,

Medical School, University of Capetown M. R. Drennan.

Rehabilitation Centres

Sir,—I enclose a brief memorandum which expresses the general opinion of the members of the British Orthopaedic Association in regard to rehabilitation, and I am doing so at the request of some of the senior members of the Association. We feel that it should be clearly understood that the orthopaedic surgeons of the country are wholly in favour of this constructive medical and sociological movement.

I think we all feel that rehabilitation should begin very soon after the accident or wound, and be carried on throughout the patient's period in hospital in the form of occupational therapy and gymnastic or remedial exercises. There remains as a logical and very necessary development the organization of Rehabilitation Centres where the final and more concentrated stages of rehabilitation are given to enable the patient to be returned to the Services or to industry with the least possible delay.—I am, etc.,

G. R. Girdlestone,

Headington, Oxford President of the British Orthopaedic Association.

*** The memorandum runs as follows:

The members of the British Orthopaedic Association recognize the value of measures already adopted by the Ministry of Health in introducing rehabilitation into E.M.S. orthopaedic, fracture, and accident services. They are not, however, satisfied that the later stages of rehabilitation have been adequately developed throughout the country; and for this particular purpose they urge the importance of establishing special Rehabilitation Centres, in association with existing orthopaedic, fracture, and accident services; under the same administrative and surgical control, but as a rule geographically separated in order to avoid the hospital atmosphere; and affording all facilities needed for the completion of treatment right up to the stage when work can be resumed. From undoubted evidence of grave wastage of man-power through accidents, they believe that the developments recommended are of immediate urgency in the prosecution of the war.

Listerism

Sir,—I have read the correspondence on the Lister technique in your issues of Sept. 5 and 26 and Oct. 3. A good case made out can't have too much backing, but there seems some confusion as to Listerism among others who think aseptic surgery is different from what Lister taught. The three main principles of Listerism are: (1) disinfection of the skin, (2) destruction or inhibition of the germs in the wound, and (3) prevention of the entrance of germs into the wound. Lister used antiseptics to produce asepsis, and he introduced dressings and a "protective" (oiled silk). We are indebted to him for the undermentioned: In 1866 he used crude creosote for wounds and banished pyaemia from his wards. He made a "plaster-of-Paris putty" for a compound fracture and covered it with tin foil, and so paved the way to the present-day method. (This was at a time when there was no bacteriology.) He tied the carotid artery of a horse under antiseptic conditions with good results, using first kangaroo tendon; this work then led him to chromic acid catgut. He invented a spray and this led to aerial disinfection. He taught the immobilization of wounds and fractures. He showed the possibilities of skin grafting. He insisted on sharp knives, so as not to bruise tissues. He showed the correct way of giving chloroform without a death. He introduced drainage of wounds. He was the first to open a knee-joint under antiseptics. He introduced the gauze bandage and the double cyanide gauze—thus aimed at asepsis. He introduced "protective"—oiled silk coated with dextrine; it was soaked in boric solution. Here is added proof of his goal—asepsis. You can't have antiseptic treatment without simultaneous asepsis. He introduced boric ointment. He invented a sinus forceps. He introduced massage after fracture treatment. He insisted on instruments in trays being covered (asepsis). He first wired a fractured patella under antisepsis. He advocated the defensive power of human tissues.—I am, etc.,

---

Release of High-frequency Apparatus

SIR,—So much has been said of the hardship suffered by practitioners and patients from the impounding of diathermy and short-wave apparatus by the Post Office that I think it is only right, now that the restrictions have been modified, to put on record that my apparatuses have been returned to me with promptitude, efficiency, and in good working order. Although they have been stored for fully two years by the Post Office, it is pleasant to report that they have been extremely well cared for, and have come back in as good condition as they were in when they were taken away. The B.M.A. has been largely instrumental in securing this relaxation of the original order, and deserves the thanks of those who use high-frequency apparatus.

One further point I should like to mention. Although it has been considered necessary to retain screening restrictions, the Post Office have recognized the desirability of being able to treat cases without having to move them into screened cubicles. They have, in consequence, offered their technical help and collaboration in evolving an apparatus which would be free from the drawback of causing so much interference as the existing diathermy and short-wave apparatus and yet be sufficiently portable and robust that it could be taken to the bedside of patients. This would make it possible to treat cases of pneumonia, shock, and burns. Their help will be of the greatest practical value.

An experimental apparatus has already been constructed which, while itself not satisfactory, has shown the pitfalls to be avoided and also that the problem is one capable of solution. From the clinical and physical medicine point of view the use of short-wave currents in cases of shock is better than electric blankets, radiant heat cradles, and methods that have to rely on the conduction of heat from the skin. The Postmaster-General points out, however, that the supply of the necessary valves during the war may be extremely difficult. This would be overcome if, on clinical trial, the apparatus provided an improved method of combating shock.—I am, etc.,

C. B. HEALD,
London, W.1 Chairman, Physical Medicine Group, B.M.A.

Periodic Medical Examination

SIR,—It is to be hoped that the article on this subject by Dr. Frank Ellis (Sept. 26, p. 365) will arouse widespread interest. At the present time it is inevitable that experiments in preventive medicine should be side-tracked in favour of more urgent problems. The fact that the work of the Peckham Health Centre, which Dr. Ellis mentions, has had to be suspended must be considered perhaps a minor tragedy of the war. Nevertheless, those of us who have been inspired by the teachings of the late Sir James Mackenzie realize with Dr. Ellis that medical science can make little further progress without a better understanding of the early stages of disease. Further, we can only arrive at this understanding by reorganizing the medical services in such a manner as to permit of facilities for periodic medical examination of the whole population. Such facilities could be fitted without difficulty into most of the plans which have been elaborated recently.

The purpose of this letter is to point out certain difficulties and to make a concrete suggestion. Dr. Ellis mentions and discusses the work of the Life Extension Institute in New York. I was familiar with their published work, and also paid them a long visit in 1939. I was impressed by the efficiency of their organization, but I had two criticisms to make. (1) The Life Extension Institute were not able to persuade the American general practitioner to co-operate with them. In fact the overwhelming majority of practitioners were not only non-cooperative but hostile. This is a cardinal fault in any organization which sets out to do systematic preventive medicine along the lines of periodic examination. As Sir James Mackenzie emphasized at St. Andrews, the general practitioner is the most important instrument in any such scheme. It is the general practitioner who is in closest contact with the patient, his family and background. (2) A more important criticism of the Life Extension Institute is a technical one. Their methods of physical and radiological examination of each patient were beyond criticism. They had also evolved a system of careful "history" taking, which represents a real advance. But physical and *x*-ray examinations of so-called healthy people are not sufficient. If we are to detect those functional abnormalities which inevitably precede disease—the stage of symptoms (or even earlier) rather than that of signs, as Sir James Mackenzie put it—we must have a new technique of examination. This, in my view, is where the Life Extension Institute fail. Their methods are admirably adapted to the detection of early disease, but that is not enough.

I have been engaged for many years in an attempt to devise and standardize a more sensitive and comprehensive technique for this sort of examination. The vast and fertile field of applied physiology and biochemistry is open to those of us who are doing this work. Now that this subject is arousing more general interest it is desirable that all who are actively engaged in this sort of research should combine and agree upon: (*a*) A standardized technique to be used for periodic examination. If we expect facilities we must be clear as to exactly what facilities should be provided. The correspondence in the same issue of the *Journal* on the subject of methods for the determination of blood sedimentation rate is sufficient proof, if such were needed, of the desirability of standardization. (*b*) A method of approach to the general practitioner. The best method of enlisting the support of the practitioner would be to enrol him inside the framework of any such preventive organization. In the meantime articles and books should be written setting out what knowledge we have and the manner in which such knowledge, applied to practical problems, could be of invaluable assistance to every practitioner.

Finally, a suggestion. Could not a committee or subcommittee be set up for this purpose within one of the planning organizations? In peacetime this committee could be expanded to form a society which should bear the name of Sir James Mackenzie.—I am, etc.,

London, E.C.1. E. OBERMER.

"Constipation" in Breast-fed Babies

SIR,—Dr. E. F. Chapman (Oct. 3, p. 408) pertinently alludes to a principle of wide application—viz., a child should be allowed to perform its functions of intake and output with the minimum of interference. The process of "training" as to times for feeds and as to times, places, and occasions for actions of the bowel is not merely unwelcome to the natural constitution of the child, it is reacted to by many children with feelings of angry defiance, aggression, hate, and obstinacy. In her desire and anxiety to "train" her child as soon as possible, the mother, unknown to herself, may be "getting her own back" for similar interference in her forgotten childhood. Furthermore, the child has to suffer interference emanating from ignorant, alarming, and misguided ideas as to what constitutes "constipation." The child is constituted to anticipate a pleasurable satisfaction from release of tension in the rectum in accordance with the timing of its own feelings and experience, its timing being neither that of the clock nor of mother. It therefore resents any form of interference, most of all if thereby pain is substituted for pleasure, as is apt to accrue from administering purges, enemata, suppositories, and the like by anybody however wittingly well-intentioned. An enema is all too prone to become an enemy in the mind of a child, hence resistant anal spasm and more prolonged "constipation" can result, even from the very thought of one, or of its giver.

Those who are concerned with the psychogenesis of many undesirable and handicapping character traits and of many psychoneurotic symptoms are convinced of the close association between such traits and symptoms and interference with the child's natural pleasures of ingestion and of elimination by *force majeure*. An interesting example of the evil that mothers do living after them has been observed by Dr. Joan Malleson in her paper, "Vaginismus: its Management and Psychogenesis" (Aug. 22, p. 213). Under the section "Aetiology," she produces convincing evidence of the close association of this distressing disorder with anal pain of childhood. Dr. Malleson's paper merits the attention of all those concerned in the "training" of children and gratitude for her original observation of yet another malady that, in some cases, is otherwise inexplicable than by unwarranted and cruel "training." We live and learn!—I am, etc.,

London, W 1. R. Travers Smith.

Sir,—Your correspondent Dr. E. F. Chapman (Oct. 3, p. 408) disagrees with Prof. Charles McNeil's remarks in his alphabet of breast-feeding on "one type of constipation." No experienced paediatrician, least of all Prof. McNeil, will disagree with Dr. Chapman's observation that "large numbers of perfectly healthy breast-fed babies will only have a bowel action every two, or three, or even four days . . . there is nothing whatever the matter with these babies, and they should be left alone. The regular daily habit will establish itself later on." Dr. Chapman infers, however, that he does not believe in anal spasm, and accuses Prof. McNeil of inventing "an imaginary pathology to explain a non-existent disease." There is no doubt that such a condition exists, and it accounts for a considerable minority of the cases of infrequent defaecation in breast-fed babies. In both the habitual type of infrequent defaecation and anal spasm the stools are normal in colour and consistence, but anal spasm is characterized by excessive straining at stool, with severe congestion of the face and tight spasm of the sphincter ani muscle, which can easily be distinguished by inserting the little finger.

It is important to differentiate these two causes of infrequent defaecation so that appropriate advice can be given to the anxious mother. In the habitual type I usually explain to the mother that the small amount of residue and the contentment which occur in breast-feeding account for the infrequency, and that daily motions will be resumed when a mixed diet is introduced, if not before. Such an explanation usually persuades mothers not to interfere with spontaneous bowel action and allays their anxiety. In cases of anal spasm I advise dilatation with the lubricated little finger daily for a few days and then less frequently. There is absolutely no indication for the administration of aperients in either condition, yet most mothers and many doctors give them freely and produce a needless disturbance of intestinal function.—I am, etc.,

Edinburgh. J. L. Henderson.

Sir,—I have read with interest Prof. McNeil's alphabet of breast-feeding (Sept. 5, p. 271), and as one who is nowadays almost solely interested in the psychological side of things, I am delighted that he—so distinguished a paediatrician—should stress the importance of breast-feeding for infants whenever possible. The evidence I have been able to collect in my work establishes beyond reasonable doubt the superiority of natural over artificial methods of feeding for the psychological well-being of both mother and child. There appears too often a tendency among doctors to wean children prematurely, even when such weaning does not appear to be absolutely imperative. Dr. Mathias (Oct. 17, p. 465) seems to imply this when he ends by saying: "If artificial feeding were such a second-rate thing, why are there not more miserable children in doctors' families?" Is he not coming near to a recognition of one of the basic factors behind melancholia?

Although Prof. McNeil recognizes the possibility of psychological faults in mother and baby as giving rise to difficulties, does he not run the risk of artificially inducing them by the treatment that he advocates for constipation in the infant? It is on this account that I am reluctant to accept unchallenged his dictum that when constipation arises in breast-fed babies it should be relieved by the repeated passage of the doctor's little finger into the baby's anal canal. I have believed that constipation arising in early life will right itself if left severely alone. Psychologically it seems to be established that for a child under 6 the less physical interference it has the better, and the less the chance of a breakdown later in life. Prof. McNeil seems to have overlooked the alarming fear and primitive hate that can be aroused and stored up in the mind of a small child and the distressing psychogenic repercussions that may ensue from anal interference, the more so because the child is too young to understand what is happening. In mental research work I have had the opportunity of treating certain obsessional and border-line cases over a considerable period, and I have found definite evidence that traumatic environmental factors in infancy have played an important part in their symptom formation and character traits in the adult, and certainly have influenced their adult behaviour.

In his article Prof. Charles McNeil does not appear to go with the psychologist in these respects. To my mind the procedure he advocates runs the risk of inducing certain undesirable characteristics to develop as the child grows up. Reaction formations are liable to set in, among them shyness, asocial tendencies, over-sensitivity to criticism or control, acquisitiveness, etc., and the "difficult" adult may eventuate. Such treatment may contribute towards changing a social being into an antisocial one, in accordance with how much or how little the child has registered the feeling of having been raped. He or she may well react to the intrusion into their private affairs or "house" of the doctor's finger (however well lubricated) by repaying the compliment and later developing habits of a retaliatory nature. They would then become the over-curious person—that "nosey Parker," always poking into other people's business—or even worse, the delinquent, who "takes it out" of society by breaking into other people's houses and stealing their goods.

There is a danger, too, of reinforcing an unconscious passive homosexual bias in the male or of setting up a vaginismus in the female. (Dr. Malleson has referred to such a contingency in her article published on Aug. 22.) Fear of loss of sphincter control is a very real thing to the small child, and this is temporarily at any rate increased, with its concomitant fear of dirtying. It seems to me that no treatment that savours of violation should be administered to the very young child unless such procedure be absolutely necessary for that child's physical health, and that this is so in the technique under discussion Prof. McNeil does not appear to have established.—I am, etc.,

London A. Cyril Wilson.

Breast-feeding

Sir,—Dr. J. Gordon Mathias (Oct. 17, p. 465) states that the feed "should not be a sensuous orgy for the infant and a sexual experience for the mother." The real question is not what a breast-feed should or should not be (according to Dr. Mathias) but what in fact it *is*, physiologically. As to whether it is a "sensuous orgy for the infant" we can infer from observation of the feeding infant; we have evidence that Nature intended it to be a "sexual experience," using the term broadly, for the mother, in the well-known relation between stimulation of the breast and the uterus.

If Nature intended woman to feed infants woman should be pronograde, he argues; are our simian relatives all pronograde? As to caloric feeding for the (mythical) "classical ten-pound infant," the fallacies of rigid adherence to caloric or other fixed systems in dealing with that most individual problem—infant feeding—are common knowledge. Dr. Mathias argues that if the doctor is of the opinion that "the baby and the mother would fare better on artificial feeding, he should be equally competent to advise," but earlier in his letter he says "doctors in general know so little about infant feeding." I am afraid one must endorse both of these statements!—I am, etc.,

Darwen R. C. Webster.

Correct Use of Sulphonamides for Gonorrhoea

Sir,—May I appeal, through your *Journal*, to all practitioners to help the campaign against venereal diseases by using sulphonamides for the treatment of gonorrhoea in such ways as are calculated to make the patients non-infectious as quickly as possible and to run the least possible risk of creating sulphonamide-resistant strains of gonococci. From all parts of the country complaints are being received in the Ministry of Health that many practitioners start treating for gonorrhoea without first taking specimens for confirmation of the diagnosis, and give sulphonamides in quite inadequate dosage. Failure to take specimens makes it very difficult, whenever the symptoms have not abated or elapsed, to decide if the original infection was or was not gonococcal because gonococci may have been merely driven to ground by the remedy. Inadequate dosage may abate the symptoms without eradicating the infection; thus by creating in the patient's mind the impression that he is cured it conduces to the spread of the disease. The evidence that it is possible to create sulphonamide resistance in gonococci by underdosage is sufficiently strong to warrant every effort to avoid it, because the spread of such strains throughout the country would take our anti-gonorrhoeal measures back to the pre-sulphonamide era. A timid dosage with sulphapyridine may perhaps be understandable when the infection is not life-endangering and the patient is ambulatory, because of the toxic effects of this remedy, but there is no reason for it in the case of sulphathiazole, which is now available in sufficient amounts for the eradication of gonorrhoea from the community.

There is now good evidence that administration of 5 grammes of sulphathiazole on two successive days eradicates the disease, in males at least, in over 90% of cases, and four days' treatment on the same lines affords still better results; in neither case does such a dosage give rise to any undue proportion of toxic effects, provided that the patient is made to drink plenty of water during the period of the chemotherapy. It requires only slight imagination to see the possibilities of this treatment from the point of view of the public health, if only all members of the profession will collaborate in exploiting it properly.—I am, etc.,

Ministry of Health, S.W.1. L. W. HARRISON.

SIR,—In view of the great importance of the control of gonorrhoea among the civil population, especially in wartime, I should like to draw attention to one easily avoidable hindrance to attaining this end. I refer to the common and, to judge by this clinic, increasing custom of practitioners to give sulphapyridine (M & B 693) at sight in cases of urethritis. Not only is this done without any bacteriological confirmation of the diagnosis, but, what is even more serious, the doses and rate of administration of the drug—e.g., one tablet t.d.s. for perhaps ten days or more—are often almost perfectly calculated to produce a drug-resistant strain of organisms. Only after this regime has been continued for a week or two and has failed to clear up the discharge is the patient referred to a clinic, by which time, it will be agreed, both diagnosis and treatment have been rendered considerably more difficult than they need be.—I am, etc.,

Croydon V.D. Clinic. P. W. HAMOND.

First-aid Treatment for Fractured Spine

SIR,—The greater part of my time in the last 3 years has been taken up with teaching and examining in first aid and other subjects for the B.R.C.S. and Order of St. John and teaching the Home Guard first aid. I have been impressed with the difficulty the first-aid student often seems to have in following and grasping the essentials of the first-aid treatment of fracture of the spine. For some time past I have thought that the instruction on this subject should be simplified and standardized. I was therefore interested to read an article in *First Aid and the Medical Practitioner*, one of the *Practitioner* booklets, on "First Aid in Fractures," by H. Osmond Clarke, F.R.C.S., of Manchester, in which he writes as follows:

> "Fractures of the spine at any level should be transported in the supine position on a hard flat stretcher, maintaining as far as possible the normal contour of the spine by inserting a small pillow or pad (e.g., a folded garment) beneath the lumbar and cervical spines. It is of the greatest importance that an individual with an injured spine should be lifted on to the stretcher with his back supported at several points. If the spine is allowed to sag excessively into hyperextension or hyperflexion, as may occur when a man is lifted by his shoulders and legs, irreparable damage may be done to the spinal cord. To summarize . . . *Spine*.—Lift the patient with his spine supported at numerous points on to a hard, flat stretcher with a pad behind the lumbar and cervical regions."

This teaching of Mr. Clarke's appeared to simplify very much the first-aid treatment of fracture or suspected fracture of the spine, and to obviate the difficult (for first-aiders) question of the location of the injury, the difficult method of turning the patient on his side, and the stretcher on its side, and placing the patient in the prone position on the stretcher, in the case of fracture or suspected fracture of the dorsal or lumbar region. As this matter is one of considerable importance, I wrote to my old friend Prof. Harry Platt and asked his opinion. He writes as follows:

> "With regard to the first-aid teaching of the immediate handling of fractures of the spine, I think there is a tendency—and it is a laudable one—to simplify the instructions. The distinction between cervical injuries and those in the dorsal or lumbar region is well enough for the expert, but liable to be confusing to those untrained people who may be called upon to move the injured person. I myself, therefore, would agree with the teaching that all spinal injuries can be *safely* transported in the supine position, provided (i) the natural contour of the spine is maintained—e.g., by appropriate pillows; and (ii) no *flexion* movements—or, indeed, *extreme* hyperextension movements—are permitted during the lifting of the patient. I do not think this subject has been debated recently by orthopaedic surgeons, but most of them would be keen on having a simple standardized method laid down for the guidance of the non-expert. I think your scheme is sound."

The scheme to which Prof. Platt refers is one which I suggested should be used as a standardized treatment for all cases of fracture or suspected fracture of the spine at any level by all first-aiders as immediate treatment. In all cases where there is a history of accident or injury to the neck or backbone with pain and shock, even though there is no paralysis of arms and/or legs, treat as follows:

> (i) Warn the patient not to try to move; (ii) keep him warm; (iii) send for the doctor, and if there is any chance of getting medical assistance in a very short time, *do nothing more* till the doctor comes; (iv) if there is no chance of getting medical assistance within a reasonably short space of time, and (v) if you have trained assistants with blankets, triangular bandages, and stretcher, (vi) proceed as follows: if the patient is found in any other position except on his back, with great care and all the assistance possible turn him gently on his back; (vii) tie the lower limbs together by applying broad triangular bandages round thighs and knees, and a figure-of-8 bandage round both feet and ankles; (viii) five broad triangular bandages are passed under the natural hollows of the body, so that they come to lie under his head, chest, hips, thighs, and calves; (ix) two strong poles are used and the bandages are looped or tied round the poles, and the patient is slowly and gently lifted on to the stretcher by two or, if possible, three assistants on each side; (x) the stretcher, which is hard and flat, is prepared by folding the blankets as in the Army method, with a small pad or cushion made out of folded garments placed on the stretcher behind the cervical and lumbar regions respectively.

It will be seen that this method incorporates the teaching of Prof. Platt and Mr. Osmond Clarke (to whom I am very grateful), together with other details already in use, and it is for the immediate first-aid treatment of fracture or suspected fracture of the spine at any level. I think not only orthopaedic surgeons but also teachers and students of first aid would welcome some such simplified standardized method of treatment.—I am, etc.,

Subcutaneous Ligature of Varicose Veins

SIR,—As the originator, to the best of my belief, of this method I should like to express my gratification that Major E. L. Farquharson (Oct. 17, p. 453) has found it useful.

Further experience has somewhat improved the original technique (*B.M.J.*, 1941, **1**, 626). I find Mr. Dickson Wright's method of introducing the stitch through a hypodermic needle rather easier than using a curved needle, and I have given up the standing position for the patient. If the position of the vein is marked on the skin with ink in the standing position it is quite easy to carry out subsequent manipulations while the patient lies down. I still use the intradermal wheals of novocain, which take very little more time, and certainly relieve the patient of some discomfort.

As regards the permanence of the method, I have had a recurrence in a case of ectasia which required Trendelenburg's operation, but my other cases are still satisfactory, after more than two years in some of them. Whatever theoretical objections may be raised, the fact remains that the method is successful and that no hospitalization is required while the patient is being treated, which would be impossible for injection alone. Incidentally, several of these people who have been treated by subcutaneous ligature are among my most grateful patients.—I am, etc.,

Bradford. H. S. RUSSELL, M.D.

Shock Treatment in Psychiatry

SIR,—I would like to comment on your leading article on shock treatment in psychiatry (Oct. 3, p. 397). While one must fully agree with the need for systematic and planned treatment in psychiatry and also regret the tendency to regard electro-convulsant therapy as a panacea, yet it would appear a mistake to consider insulin shock and electro-convulsant treatment as therapeutically discrete.

Your article makes the important point of the need for standards of diagnosis and prognosis; and surely it is here that the schizophrenias produce the most difficult problems. Most psychiatrists would agree that the term "schizophrenia" covers a group of more or less closely related syndromes, and the value of insulin may be found greater in the schizophrenia-like psychoses than in true dementia praecox, or possibly even the other way round. In the former group of psychoses we can certainly claim some striking results with electro-convulsant therapy. In this clinic, for example, we have seen the resolution of thought disorders, depersonalization, in fact every kind of schizophrenia-like symptom-complex.

We do not assert that electro-convulsant therapy should replace insulin, but I feel sure that the time has not yet come for any generalizations upon their respective merits. We should base our therapy on the most prolonged and careful observations, and to this end one must again reaffirm the need (expressed in your columns in 1940) for more clearly defined criteria in psychiatry.—I am, etc.,

JONATHAN GOULD, M.B., B.Sc.

Department of Psychological Medicine,
St. Bartholomew's Hospital.

Prevention of Small-pox

SIR,—Now that the outbreak of major small-pox in Glasgow is at an end it is permissible to discuss the question of the measures taken to combat it, and, in particular, the effort made to secure the mass vaccination (or revaccination) of the entire population of the city. It will not be disputed that such a measure is a serious one to take from more than one point of view. Vaccination is a much more serious operation than, say, immunization against diphtheria. In the majority of cases it constitutes a definite interference with health, and, although this is usually only temporary, it often lasts for over a week, and occasionally for very much longer. It is often serious enough to necessitate absence from work for several days or a week, and it may affect working efficiency even though the individual continues at work. We are told that the total number of persons vaccinated in the Glasgow campaign was 378,000. It would be interesting to know (were the figures available) the total amount of time lost from work as a consequence, direct and indirect, of all this vaccination.

Moreover, a vaccination drive, such as must have been practised in Glasgow, inevitably gives rise to, or at least must have greatly intensified, public alarm and upset—i.e., "scare," a psychological condition scarcely conducive to maximum productive efficiency. Lastly, the great administrative effort required for a vaccination drive on this scale must, it is reasonable to suppose, have tended to divert effort from really important measures such as the effective following up and control of contacts.

If promiscuous mass vaccination of a community were really essential for controlling an outbreak of small-pox and preventing it becoming a serious menace, not only to the city in question but to the whole country, then the effort, costly though it be in the ways indicated, could doubtless be justified. But is it essential? Surely the evidence available from the behaviour of major small-pox in the past half-century is all against such an assumption. During this period the proportion of the population protected against small-pox by vaccination has continuously declined, until it is now only a minority, yet the disease has shown itself less and less able to establish itself in this country, although it has been introduced again and again, sometimes under conditions apparently very favourable for spread.

Take the case of Leicester, with which city I am best acquainted, having been M.O.H. there for over 30 years (1901 to 1935). During my term of office I had to deal with a number of outbreaks of major small-pox, but mass promiscuous vaccination of the population was never attempted, or indeed advocated. Yet the disease never got out of hand, still less was there any general conflagration—as had been so often prophesied—and this in spite of the fact that the general population was, for all practical purposes, entirely unprotected by vaccination. Thus, during the 50 years 1885 to 1934 the percentage of children vaccinated averaged only 8.5. During the same period the total deaths from small-pox numbered only 53 in an average population of, say, over 200,000. Other towns have had a similar if less striking experience. In view of this, what serious grounds are there for thinking that general vaccination of the population plays any important part, under modern conditions, in the effective control of small-pox?

To prevent possible misapprehension may I say that I have a profound belief in the utility of selected individual vaccination—e.g., in protecting sanitary and hospital staff, and (to a less extent) in protecting actual contacts.—I am, etc.,

Leicester. C. KILLICK MILLARD

"Duodenal Ulcer Battalions"

SIR,—Large numbers, probably many thousands, of men suffering from duodenal ulcer (and allied conditions) are being discharged from the fighting Services. The majority of these individuals are the best type of fighting man—sthenic, energetic, vigorous, and of high courage; many are discharged against their wishes. Is there any insurmountable reason why their services should not be retained? Why not form battalions or even divisions of "duodenal ulcers"?

With collaboration between the Ministries of Health and Food and the medical branches of the Services provision for feeding and the treatment of large bodies of men should present no real difficulty. Indeed, it should be easier and more economical to cater for, say, a thousand men living together under strict discipline than for the same number scattered throughout the country in individual homes.

And what a field for research: an opportunity which is not available in peacetime! Few will claim that our present methods of treatment of duodenal ulcer are entirely satisfactory. Medical treatment is generally inadequate: the surgical operations in vogue are drastic and crude.—I am, etc.,

Dundee. F. R. BROWN.

Interchangeable Shoes

SIR,—In the annotation on laterality, dominance in Shakespeare (Oct. 10, p. 432) it is remarked that Dr. Johnson made the "surprising comment": "He that is frighted or hurried may put his hand into the wrong glove, but either shoe would equally admit either foot," and Sir Walter Raleigh inferred that Dr. Johnson possibly wore his boots indifferently, "either on either foot," and believed that other people did the same thing. Is it not possible that in Johnson's time boots and shoes were made for either foot indifferently?

Lord Cockburn, in *Memorials of His Time*, a classic volume dealing with life in Edinburgh, especially the life of the Bench and the Bar, in the beginning of the 19th century, describes his outfit when he was first sent to the Edinburgh High School in 1787. He was provided, among other garments, with "brown corduroy breeches, tied at the knees by a showy knot of brown cotton tape; worsted stockings in winter, blue cotton stockings in summer, and white cotton for dress; clumsy shoes made to be used on either foot, and each requiring to be used on alternate feet daily; brass or copper buckles."

Some square-toed shoes seen on statues and in portraits of the 16th and 17th centuries appear as if they could be worn on either foot as the wearer inclined. Long pointed shoes of a much earlier period, such as those worn by the Prior of Jorvaulx in *Ivanhoe*, were almost certainly interchangeable for the feet.—I am, etc.,

Glasgow JOHN PATRICK.

The King has granted Dr. Harry Chapman Sinderson, C.M.G., M.V.O., O.B.E., Dean of and Professor of Medicine in the Royal College of Medicine of Iraq, authority to wear the Insignia of the Second Class of the Order of El Nahda conferred upon him by

Obituary

LEONARD KIDD, M.D.

The death has taken place at Enniskillen, Northern Ireland, of Dr. Leonard Kidd, who for forty years held the post of medical superintendent of Fermanagh County Hospital, and for thirty-six years was direct representative for Ireland on the General Medical Council. Dr. Kidd, who was in his eightieth year, had been ill for a long time.

He was a native of County Louth and spent his early youth in Armagh. At one time he was a master at Foyle College, where he taught classical and modern languages. He was a keen player of rugby football, and once played for Ireland. He received his medical training at Trinity College, Dublin, and at Edinburgh, qualifying L.R.C.P.&S.I. in 1887, and taking his Dublin medical degrees in the following year. After various hospital appointments he settled in practice in Enniskillen, where his "monument" is the county hospital which he served as medical superintendent for so many years with marked ability and devotion. He transformed the institution from a comparatively small, poorly equipped building for the aged and infirm into one of the most modern and best furnished hospitals in all Ireland. It was no longer necessary for patients, well-to-do or poor, to undertake the hundred miles' journey to Dublin to undergo an operation. A theatre was installed, trained nurses introduced, proper accommodation for nurses provided, and the progress went on until, just before his resignation in 1937, a new maternity ward and children's clinic were added. Dr. Kidd was also for forty years medical officer to Portora Royal School, and took a deep interest in the welfare of its boys, including its old boys. A portrait of him was unveiled in the hall of the school early during the present year. He was president of Enniskillen District Nursing Society, and the high state of efficiency of nursing in Fermanagh was due largely to his efforts. For a time he was a member of his urban district council, where he zealously advocated improved housing, water supply, and sanitation.

In medical politics he was a prominent figure. One of his ideals was a Ministry of Health for Northern Ireland, and he had many consultations with the Prime Minister, the late Viscount Craigavon, and the Ministry of Home Affairs on the subject, but his advocacy was unavailing. He became a member of the British Medical Association as long ago as 1889, and in 1906 he was a very acceptable president of the Ulster Branch. He had also been chairman of his own, Fermanagh, Division. When the Association visited Belfast in 1937 he acted as vice-president of the Section of Medical Sociology. He had also been president of the Irish Medical Association (now merged with the B.M.A. in the Irish Free State Medical Union). His long membership of the General Medical Council, from 1906 until quite recently, introduced him to prominent medical men in Great Britain, by whom he was greatly esteemed. In the war of 1914-18 he served in the R.A.M.C., holding the rank of major. A deserved honour which came to him a few years ago was his appointment as Deputy Lieutenant for his county.

LOUIS C. PARKES, M.D.

The death of Dr. Louis Coltman Parkes at the age of 84 will recall to senior members of the Public Health Service a man who in his day did notable work in sanitary science and was long known to students and practitioners as the author of a standard textbook on hygiene which passed through eight editions. From University College Hospital he graduated M.B.Lond. in 1880 and M.D. in 1882, and he was one of the first to take the D.P.H. For many years Dr. Louis Parkes was medical officer of health for Chelsea and consulting sanitary adviser to H.M. Board of Works, retiring from the service of the Metropolitan Borough of Chelsea in 1923; he was also honorary sanitarian to the East End Maternity Hospital. He had been vice-president of the Royal Sanitary Institute, and was a Foreign Associate Member of the Société Française d'Hygiène. He held office at three Annual Meetings of the British Medical Association—as honorary secretary of the Section of Public Medicine in 1890, vice-president in 1895, and president of the Section of Hygiene and Public Health in 1909. He was the originator and sole author of the early editions of *Hygiene and Public Health;* Prof. H. R. Kenwood joined him later as co-author of that work, and collaborated in 1929 with Prof. Harold Kerr in preparing the eighth edition. Dr. Parkes also wrote small books on *Infectious Diseases. Notification and Prevention* in 1893, on *Elements of Health* in 1895, and on *House Drainage, etc., in Relation to Health* in 1909. He edited the third edition of Corfield's *Treatment and Utilization of Sewage.* He died in retirement at Holmbury St. Mary, near Dorking, on Oct. 11.

Dr. Robert Applegarth Hendry died at Rugby on Aug. 13, and medicine was the poorer for the loss of a general practitioner and gynaecologist who overcame his own disabilities in so heroic a manner that his fellows and patients always looked to him as the leader of local medical thought. He was a sufferer from arthritis for many years, but this he never allowed to interfere with the needs of his patients. He was always the same kindly administrator to the sick and suffering, wherever or whenever he was called. I have watched him operate late at night, and his thoughtfulness towards the theatre staff was a model for any young surgeon. Whenever a meeting was held at which controversy might arise he was an automatic choice as chairman, so respected was he by his colleagues for scrupulous fairness and honesty of thought. His academic career was brilliant, and he took the gold medal at the M.D.Lond. examination in obstetrics and gynaecology in 1908. He then became demonstrator of obstetrics and gynaecology, subcurator of the obstetrical and gynaecological museum, and Ethel Boyce Fellow, University of Liverpool; and honorary assistant gynaecological surgeon, Hospital for Women and Liverpool Royal Infirmary. When the highest honours in his specialty appeared within his reach, illness snatched them from him, and in 1925 he gave up his work in Liverpool and entered general practice. His love for gynaecology was so strong that in 1936 he again took up hospital work, joining the honorary staff of the Hospital of St. Cross, Rugby. He was elected chairman of the Medical Board, was chairman of the Rugby Division of the B.M.A., and had held the chair of various other committees, including the local Rotary Club. Dr. Hendry leaves a widow and two sons. The elder, Capt. Preston Hendry, R.A.M.C., is on active service in the Middle East. Shortly before his death Dr. Hendry received the news that this son had been mentioned in dispatches.—P. T. D.

Universities and Colleges

UNIVERSITY OF OXFORD

Dr. Alexander M. Cooke, F.R.C.P., May Reader in Medicine, has been elected to a professorial fellowship at Merton College.

In Congregation on Oct 20 a decree was passed establishing a professorship of social medicine. This gives effect to the decision announced in these columns on July 25 (p. 101) to establish at Oxford an Institute of Social Medicine and to appoint a professor to be in charge of it. The Nuffield Provincial Hospitals Trust will devote £10,000 a year for the next ten years for the purposes of the chair and the institute in which the professor will work.

UNIVERSITY OF CAMBRIDGE

Prof. H. R Dean, M.D., Master of Trinity Hall, has been elected the representative of the University on the General Medical Council for the five years from Oct. 22, 1942

The late Sir Joseph Larmor, F.R.S., has bequeathed to the University £2,000 to be devoted to providing medical and surgical assistance and sick nursing to junior members of the University.

At a Congregation held on Oct. 16 the following medical degrees were conferred by proxy:

M.B., B Chir —R. M. Emrys-Roberts, A J. Rook, W F. Felton, M Koettlitz, J. B. Stanton, G. Wetherley-Mein, I. N. Darbyshire, M. M. Brown, K. H. Lim, W. P. U Jackson, R. J. F. H. Pinsent.

M.B —J. Mackellar

Cecil Clifford Dobell, M.A., F.R.S., of Trinity College, protistologist to the Medical Research Council, has been approved for the degree of Doctor of Science.

UNIVERSITY OF SHEFFIELD

Drs. H. Le Brun and W. A. Harney have been appointed temporary demonstrators of anatomy. The University Council has accepted, with regret, the resignation of Mrs. M. G. Happey, M.B, of the post of assistant bacteriologist, and has accorded its thanks to Dr. Happey for her services.

QUEEN'S UNIVERSITY OF BELFAST

Dr. William Lyle, a medical graduate of Queen's University, Belfast, and County Director of the Red Cross in that city, has been returned unopposed as a representative of Queen's University in the Northern Ireland Parliament, to fill the vacancy caused by the death of Col. A. B. Mitchell, F.R.C.S.I.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

It is proposed to hold a meeting of Fellows and Members at the College in Lincoln's Inn Fields on Thursday, Nov. 19, at 2.30 p.m., when a report from the Council will be laid before the meeting.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At a meeting of the Royal College of Surgeons of Edinburgh, held on Oct. 21, with Mr. J. W. Struthers, President, in the chair, the following who passed the requisite examinations were admitted Fellows:

W. R. Black, D. G W Clyne, P. G. L Essex-Lopresti, T. B FitzGerald, R A Fleming, L. Gillis, E. Gledhill, J. E. V. Jones, A N Reid, E. L. Salingar, M. Sugar, H. Winter

The Services

CASUALTIES IN THE MEDICAL SERVICES

In an Admiralty list of casualties in H.M. minesweeper *Leda*, published on Oct. 16, the name of Temp. Surg. Lieut. WILLIAM WILSON TENNANT, R.N.V.R., is included as "missing, presumed killed." He was born on May 21, 1909, and was educated at the University of Glasgow, where he graduated M.B., Ch.B. in 1940. He entered the R.N.V.R. soon after qualification.

Surg. Lieut.-Cmdr. MAURICE CAY, R.N., who is reported "missing, presumed killed" in Oct., was the son of the late Capt. Cay, R.N., and graduated M.B., Ch.B. at the University of Edinburgh in 1934. After holding the post of assistant medical officer at the Hope Hospital, Salford, he entered the Royal Navy in Jan., 1935, and was recently promoted. He leaves a widow.

Missing.—Lieut. P. T. Chopping, R.A.M.C., Capt. L. B. Gunn, R.A.M.C., Temp. Surg. Lieut. B. H. O'Neill, R.N.V.R, Surg. Lieut. J. G. Reed, R.N.V.R.

Medical Notes in Parliament

Nutrition Council

On Oct. 20 Sir E. GRAHAM-LITTLE asked whether the Parliamentary Secretary to the Ministry of Food would consider the desirability of setting up a Nutrition Council, consisting of clinicians, laboratory workers, and medical officers of health, as urged from many authoritative quarters. Mr. ERNEST BROWN, who replied, said: I have read with interest the expressions of opinion about possible developments in the realm of nutrition, and have had an opportunity of discussing them with my colleagues. Though the advocates of the establishment of a Nutrition Council appear to differ somewhat among themselves both about methods and objects, the main purposes which they appear to have in view are already secured by existing arrangements. Technical investigation and research are adequately provided for through the Medical Research Council, the Agricultural Research Council, and the Department of Scientific and Industrial Research. A great volume of work is continuously in progress under the auspices of these bodies, and the first-named comprises among its members and officers a number of scientists outside the medical profession, and from the outset much valuable research on nutritional problems has been conducted on its behalf. The application to current problems of the results of scientific investigation is primarily the responsibility of the Health Departments, to which the Ministry of Food and the Agricultural Departments look for guidance in nutritional matters when framing their programmes of production, import, and distribution of foodstuffs Co-ordination of the policies of the various Ministries concerned is fully provided for by appropriate interdepartmental machinery. As regards the international aspects of the subject, the Allied Governments last year appointed an interallied committee to prepare estimates of post-war relief requirements, and I understand that this committee has already arranged for a subcommittee of Allied nutrition experts to examine the estimates from the nutritional standpoint.

Mass Radiography

Mr. ERNEST BROWN stated on Oct. 15 that production of the standard apparatus for mass radiography had not reached a stage at which its cost could be closely determined, but it was expected to be in the region of £1,500. Apparatus of this kind was not subject to purchase tax. It was not proposed to make special grants towards this particular item of cost to those county councils and county borough councils who would be concerned, but Exchequer assistance was given towards the cost of the treatment of tuberculosis.

Diphtheria

Replying on Oct. 15 to Mr. James Griffiths, Mr. BROWN said the number of cases of diphtheria notified during the first three quarters of this year was 29,939. This represented a decrease of about 6,500 on the corresponding period last year. The provisional mortality figures for the first half of 1942 showed a decrease of 0.8% on the corresponding figures for 1941.

Making Sea-water Drinkable

The Department of Scientific and Industrial Research has investigated on behalf of the Minister of War Transport various methods of converting sea-water into drinking-water, and the conclusion has been reached that the most suitable apparatus for use in a lifeboat would be a small still. Such a still must have a high standard of efficiency in view of the restricted space available for storage of fuel in lifeboats Experimental stills have been made and are now under test.

The Glasgow Small-pox Outbreak

Mr. LEACH inquired on Oct. 14 whether the Glasgow sanitary authority had tried to ascertain the vaccinal condition of the electrical engineer who was found to be suffering from confluent small-pox when removed to hospital from a steamer at Glasgow on May 29. Mr. JOHNSTON said this patient had been too ill to be questioned and the vaccination marks, if any, could not be seen because of the rash. The patient's companions stated that he had never been vaccinated. Inquiries to his relatives would have been difficult because they were in Australia. Answering further questions on the same date, Mr Johnston said that when the outbreak began revaccination was offered to all staffs likely to come into contact with small-pox. A medical officer was vaccinated on May 29 without success, after he had been in contact with infection on a ship. The shipping company was not responsible for notifying small-pox on this ship, as the ship's doctor had diagnosed the case as measles complicated with pneumonia. No blame attached to a ship doctor who made a mistaken diagnosis in good faith. The case was recognized as small-pox on admission to hospital.

Fees for Medical Certificates

On Oct. 20 Mr. MOLSON asked the Minister of Health whether he proposed to take powers to restrict the fees charged by doctors for certificates recommending extra diet or fuel on account of ill-health. Mr. BROWN replied in the negative, but said he understood that the B.M.A. had recommended practitioners to forgo any fees for certificates of this kind where they believed that hardship would result to the individual.

Prevention of Frost-bite in Seamen.—Full instructions have, Mr NOEL BAKER announced on Oct. 14, been given by the Minister of War Transport to seamen for the prevention and treatment of frost-bite. Every man sailing in Arctic waters is provided with a rubberized protective suit to guard against exposure in lifeboat or raft. Oil is also provided for further protection and for massage. Other aspects of protection are under consideration.

HOSPITAL REGIONALIZATION IN LANCASHIRE

The Manchester Joint Hospitals Advisory Board, which represents the voluntary and municipal hospitals of Manchester, the University, the local Division of the British Medical Association, and the Local Medical and Panel Committee, has issued its fifth annual report, which covers the two years 1940-1. An account is given of the institution in Manchester of the blood transfusion service, whereby four hospitals are centres for the distribution of stored blood to fourteen. The service is under the general direction of the medical officer of health and the administration of a medical committee of which Dr. J. F. Wilkinson of the Royal Infirmary is chairman The other matter dealt with in the report is an account of the events following the adoption of a resolution by the Board supporting the proposals of the Nuffield Provincial Hospitals Trust, but requesting the Trust to approve of the Board being accepted as responsible for the inauguration and formation of a properly constituted regional council for a wider area. These views were accepted by the Trust, and steps have been taken for extending the area of the Board by approaching adjacent hospital authorities. An invitation has been accepted by the hospital authorities of Salford and Stretford to become members of a reconstituted Joint Hospitals Board covering these two municipal areas as well as that of Manchester. The amendments to the constitution and functions of the Joint Board are being made.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week there was a sharp rise in the incidence of the common infectious diseases of childhood. The notifications of measles, scarlet fever, diphtheria, and whooping-cough were 849, 190, 131, and 127 in excess of the previous week's totals.

The rise in the notifications of scarlet fever was fairly general, the biggest increases being in Lancashire 53 cases, Northumberland 38, and Middlesex 36. The incidence of whooping-cough was little changed in London and the southern section of the country, where there was a tendency towards a slight decline, and the increase was confined to the northern counties.

The large rise in diphtheria was contributed mainly by two counties—Lancashire, where the cases rose from 140 to 195, and Cheshire, with an increase from 39 to 78. The principal centres of infection in Lancashire were Liverpool C.B. 63, Manchester C.B. 26; and, in Cheshire, Ellesmere Port U.D., 28, had the largest number of cases.

The biggest rise in measles was in Yorks West Riding, where notifications went up from 332 to 1,123. There were 108 more cases in the C.B.s, 201 in the U.D.s, and 23 in the R.D.s, and the county contributed 24% of the total cases in England and Wales. The largest returns were those of Leeds C.B. 264, and Bradford C.B. 131. Other big increases were recorded in London and Wales, with 106 and 104 more than last week's totals. In London the rise was greatest in St. Pancras, with 49 more cases than the previous week. The chief centres of infection in Wales were Flint (Rhyl U.D. 22), Glamorgan (Cardiff C.B. 22), and Merionethshire (Ffestiniog U.D. 21).

In *Scotland* the chief feature of the returns was the rise in the notifications of measles from 185 to 303: the rise was confined to the counties of Lanark and Renfrew, with Lanark County 52, Glasgow Burgh 26, Greenoch Burgh 56, and Paisley Burgh 68. The only other outbreaks of note were in the cities of Aberdeen 33 and Dundee 31. Diphtheria has been slowly rising in incidence, and the 220 cases notified constituted the largest total during recent months, almost half of these cases, 99, being reported in Glasgow.

In *Eire* the incidence of acute poliomyelitis remained at a high level with 28 cases; they were scattered throughout the country and involved fifteen areas.

In *Northern Ireland* scarlet fever, with an increase from 34 to 60 cases, was the only disease to show any marked variation. One-half of the cases were recorded in Belfast.

Dysentery

The notifications of dysentery are still at a very high level, but there was a slight fall, 23, in the total. A new outbreak was reported from Devonshire, 26 cases occurring in Barnstaple M.B. Essex was the only one of the existing centres of infection where a considerable drop, from 33 to 4, took place. In Norfolk the cases rose from 13 to 18, involving five administrative areas, and in Yorks North Riding from 25 to 30 (notifications for the week under review in Middlesbrough C.B. 28). In Wales there was a rise in Glamorganshire, Cardiff C.B., from 30 to 36, and in Caernarvon, Conway M.B., a drop from 13 to 8. 16 cases were reported in London, and also in Southampton (Droxford R.D. 12).

Small-pox

Further cases and deaths have been reported from the outbreak at Methilhill, Fife. According to the daily press, up to Oct. 23 there have been 7 deaths and 21 cases in hospital; there were over 100 direct contacts.

In reply to questions in the Commons, Mr. Johnston, Secretary of State for Scotland, stated that the amount paid by the Glasgow Corporation for lymph used in the recent small-pox outbreak was £5,402, of which £1,075 was recoverable from the local authorities of adjoining areas. In addition lymph to the value of £6,000 was supplied by the Department of Health for Scotland. 358 doctors and 190 senior medical students received fees for vaccinations, the largest individual amount paid being £271 2s. 6d.

Returns for the Week Ending October 17

The returns of infectious diseases in England and Wales during the week included the following: scarlet fever 2,703, whooping-cough 907, diphtheria 971, measles 5,796, acute pneumonia 608, cerebrospinal fever 59, acute poliomyelitis 24, dysentery 165, paratyphoid 6, typhoid 6.

Dr. Edmond R. Long, professor of pathology and president of the American Association for the History of Medicine, and Dr. Henry E. Sigerist, director of the Institute of the History of Medicine at Johns Hopkins University, have been elected honorary members of the Society of the History of Medicine at Buenos Aires.

No. 40

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Oct. 10.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London) (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1942					1941 (Corresponding Week)

† Includes paratyphoid A and B for Northern Ireland.

‡ Owing to evacuation schemes and other movements of population birth and death rates for Northern Ireland are no longer available.

Medical News

A meeting of the Manchester Medical Society will be held at the Medical School, University of Manchester, on Wednesday, Nov. 4, at 4 p.m., when Sir Charles Wilson, P.R.C.P., will deliver an address on "Morale in Leadership." All graduates and students of medicine are invited to attend.

Prof. W. V. Mayneord, D.Sc., will give a discourse on "The Measurement of Radiation for Medical Purposes" at the Royal Institution, 21, Albemarle Street, W., on Friday, Nov. 6, at 5 p.m.

A meeting of the main executive committee of the Medical Superintendents' Society will be held at Station Hotel, Derby, on Saturday, Nov. 7, at 11 a.m.

An appointments system for out-patients will be instituted at St. George's Hospital from Nov. 2. Private and panel doctors are asked to co-operate by telephoning to arrange appointments with the appointments clerk at the hospital (Sloane 7151).

The *Zentralblatt für Chirurgie* of July 4 is dedicated to Prof Carl Henschen, director of the surgical clinic at Basle. The issue contains his portrait, a foreword by Prof. Sauerbruch, and several articles by his Swiss colleagues.

The *Yorkshire Post* announces that a gift of £50,000 is to be made to the General Infirmary at Leeds by Mr. Charles Brotherton to cover the cost of building and equipping the private patients' wing which was opened in November, 1940. This new benefaction will make available from the Infirmary's special appeal fund a similar sum for proceeding with other much-needed extensions and developments after the war. The private patients' wing gives accommodation for 90 patients, and 79 beds are now in commission.

Nursing mothers are to be allowed priority supplies of eggs for 12 instead of 6 months, but doctors need only issue an initial certificate at the time of birth, the local food office arranging the priority thereafter automatically.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, London, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C 1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

Telephone No.—B.M.A. and *B.M.J.*: EUSTON 2111.

Telegraphic Addresses.—EDITOR, *Aitiology Westcent, London*; SECRETARY, *Medisecra Westcent, London*.

B.M.A. Scottish Office: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

First-aid Treatment of Wounds

J. R. L. writes: I am lecturing to a St. John Ambulance class on first aid, and I have stressed the importance of antiseptic measures in dealing with such wounds as they may have to treat. It occurred to me to suggest that bad wounds might be well sprinkled with sulphanilamide. I will be much obliged by an authoritative opinion on the advisability of recommending such a procedure to first-aid workers.

Reconditioning of Corks

Dr. C. **Heap** writes: It is grossly wasteful to throw away corks from returned empty medicine bottles. Boiling, though it sterilizes, produces a dirty-looking cork which I do not like to use. Can anyone tell me of a method of bleaching suitable for use in general practice?

LETTERS, NOTES, ETC.

Aid for the Women and Children of Abyssinia

In these days of so many deserving appeals to individual generosity it is often a help to be reminded of causes which, by their nature, can lay some claim to support from the medical profession. One such cause is that of the Ethiopian Women's Work Association, which was first started to provide medical supplies and comforts for the troops in Abyssinia, but which is now tackling the even more difficult task of social welfare work among the women and children of that country. The London office of the association has recently received an urgent request for a woman doctor and for a social welfare worker to go out to Abyssinia to open clinics for women and children in all parts of the country, and to organize homes for children who, through the war, have been separated from or lost their parents. For this a minimum of £3,000 is needed. £1,000 has been received as a result of a broadcast appeal in September, but the balance and more is needed at once if this humanitarian work is to proceed at all It is hoped there will be a generous response to the appeal. Donations should be sent to Lady Barton, Hon. Treasurer, 19, Neville Street, London, S.W.7.

Treatment of Furunculosis

Dr. A. I. **Cemach** writes from Capel Garmon, N. Wales: The type of "furunculosis" described by Dr. G. L. Davies (Sept. 19, p 351) was well known to Austrian doctors in the last war. It was eventually overcome by a single treatment which proved to be as specific as SUP 36 in Dr. Davies's case. A 15% solution of formaldehyde was applied locally to the initial papule and its surroundings as early as possible, and repeated once or twice a day, with slight covering of the lesion to prevent chafing. As a rule the papule was arrested by this and dried up within a couple of days, no further crops appearing after two or three lesions had been checked in that way.

Naphthalene in Bedrooms

Dr. E. B. **Hazleton** (Torquay) writes: It is not generally known that the vapour from naphthalene as used in bedrooms with the object of preventing the depredations of moths may be injurious to human beings. I have noticed the following symptoms: a feeling of weariness and lassitude in the morning with loss of appetite and a muddled head.

MEDICINE 100 YEARS AGO

Extract from a letter from John Barrett to the *Provincial Medical Journal*, published on October 29, 1842:

"Gentlemen,—If we may judge from some late communications to your Journal and the 'Medical Gazette,' the *questio vexata* of what is Asiatic cholera has yet to be solved. Thus, we have on the one side two cases of Asiatic cholera forwarded you by Mr. West, of Poole, and one to the 'Medical Gazette,' by Dr. Ayres, of Thame ('Medical Gazette,' Sept. 30), whilst on the other we have Mr. Salter, a gentleman of thirty years' experience in the locality of Mr. West's cases, giving us an article on the 'Diagnosis of Asiatic and English Cholera,' in which, though he courteously disclaims any 'desire to impugn the correctness of your very respectable correspondent's observations,' he urges the importance of correct diagnosis, and in the latter part of his article remarks with respect to what he terms the 'genuine oriental cholera' 'In the first case that came under my observation, I felt that I was in the presence of a new disease, and that what I then witnessed I had never before seen; and I have no hesitation in saying that, since the disappearance of that epidemic, nothing resembling it has crossed my path.' There can be no misunderstanding this; he considers Asiatic cholera, if cholera at all, to be a cholera sui generis, whilst the communications of Mr. West and Dr. Ayres would lead us to the conclusion that they consider 'the Asiatic cholera itself,' to quote the words of Dr. Ayres, 'may be nothing more than an aggravated form of the disease so long familiar to us.'

"On which side does truth rest? No doubt, if we consider the intensity of the cholera such as it appeared in 1831-2-3, it was a new disease; at least, for my own part, I have seen nothing approaching to it in this respect, and there were circumstances attending it which I have never met with except then—e.g., the *intense* blueness, and, if the expression be allowable, the more deadly coldness of the body during life, with the singular return of warmth and natural color after death; the insusceptibility to blisters and sinapisms at the commencement; and the occurrence of vesication some days after at the parts where they had been applied; and lastly, the much talked of post-mortem muscular action—circumstances which, no doubt, were witnessed by most medical men conversant with cholera at the period in question.

"Few of your readers will, I think, dissent from Mr. Salter's opinion that rice-water evacuations, spasmodic tension of the muscles, and the blue skin cannot be considered pathognomonic of Asiatic cholera; and I must add, that whilst I allow that cholera cases do not now (at least under my observation) present us with any approach to the intensity of what was termed Asiatic cholera, yet in a modified degree they exhibit most of the symptoms mentioned by Mr. Salter as 'the symptoms belonging to the early stage of Indian cholera most to be relied upon'—viz., 'a remarkable shrinking or shrivelling up of the person, and especially of the hands, fingers, and tongue, with cold breath, and squeaking, indistinct voice, scarcely to be heard,' or, as Dr. Barry has described it, 'the low whine like that of a dog dying from arsenic.' Several of these symptoms I have seen in the cholera of this season"

THE CLINICAL SIGNIFICANCE OF THE Rh FACTOR*

BY

K. E. BOORMAN B. E. DODD, B.Sc.

AND

P. L. MOLLISON, M.B., M.R.C.P.

The discovery of the Rh factor† (Landsteiner and Wiener, 1940) and the demonstration of its importance in various fields of medicine (Wiener and Peters, 1940; Levine, Katzin, and Burnham, 1941) have recently aroused the greatest interest. Not only has an explanation now been found for many of the hitherto unexplained haemolytic reactions following certain homologous-group blood transfusions, but also a dramatic advance has been made in the understanding of the haemolytic anaemias of the newborn.

It is well known that human erythrocytes contain, in addition to the A and B agglutinogens of Landsteiner, a variety of antigenic components. These other antigens, of which M and N have hitherto been the best known, are usually ignored by clinicians in the selection of blood donors because the corresponding antibodies occur only very rarely in human sera, and, moreover, these factors, although they act as antigens when injected into certain animals, very rarely stimulate the production of immune antibodies in man. By contrast, the importance of the Rh factor lies in its ability to stimulate the formation of specific immune agglutinins in man.

The presence of the Rh factor in certain human erythrocytes was first discovered by testing samples with anti-rhesus sera, prepared by injecting the blood of rhesus monkeys into rabbits. It was found that 85% of human bloods, irrespective of group, were agglutinated, whereas 15% were not. The former are termed "Rh-positive" and the latter "Rh-negative." Persons whose erythrocytes are Rh-negative are capable, under certain circumstances, of forming an antibody which reacts with the Rh antigen. This may occur after transfusions of Rh-positive blood or, probably more commonly, when a woman (herself Rh-negative) becomes pregnant with a baby whose erythrocytes are Rh-positive.

The first demonstration of the practical importance of the discovery of the Rh factor was made by Wiener and Peters (1940). These authors described 4 cases in which haemolytic reactions occurred after the repeated transfusion of blood which would ordinarily have been considered compatible. They were able to demonstrate that the sera of 3 of these patients contained an atypical agglutinin which gave identical reactions with the anti-rhesus serum. They showed that all 3 of these patients were Rh-negative and that the blood responsible for the haemolytic transfusion reactions was Rh-positive. Ten further similar cases were next reported by Wiener (1941). In many of these cases it was possible to show that the transfusion of Rh-negative blood was by contrast as successful as an ordinary compatible transfusion.

Slightly earlier, Levine and Stetson (1939) had suggested that immunization of the pregnant woman to an antigen contained in her foetus might explain the presence of atypical agglutinins in her serum and thus account for the comparative frequency of intragroup transfusion accidents in pregnant or recently delivered women. Later Levine, Katzin, and Burnham (1941) pointed out that these women in whom atypical agglutinins were found had often given birth to infants affected with erythroblastosis. They suggested that the haemolytic anaemia in the foetus might be due to the passage of the immune agglutinin across the placenta, with subsequent destruction of the foetal erythrocytes. At the same time they stated that the majority of the atypical agglutinins had been found to give reactions identical with those of anti-Rh sera.

The rôle of iso-immunization in the pathogenesis of erythroblastosis foetalis was more fully considered by Levine, Burnham, Katzin, and Vogel (1941). These workers showed that whereas only 15% of the random population were Rh-negative, of 153 mothers whose infants were affected with erythroblastosis foetalis 141 (92%) were Rh-negative. Of 76 infants and 89 husbands in this group who were tested, all were found to be Rh-positive. In 70 cases the mother's serum was examined within two months of delivery; Rh antibodies were demonstrated in 33 of these. From this examination it was concluded that iso-immunization of an Rh-negative mother to the Rh antigen contained in her (Rh-positive) foetus, with subsequent passage of the immune anti-Rh agglutinin back across the placenta, was the cause of the erythroblastosis in the great majority of cases. In the small remaining group, in which the mother was Rh-positive, it was considered that other blood group differences were responsible. Attention was drawn to the fact that 8 out of the 141 mothers had had severe transfusion reactions although homologous-group blood had been used (but no attention had been paid to the Rh grouping of the donor). In the same paper it was claimed that the affected infant maintains higher levels of haemoglobin and R.B.C. counts after transfusion of Rh-negative blood than after transfusion of Rh-positive blood.

The heredity of the Rh factor was considered by Landsteiner and Wiener (1941). They suggested that two allelomorphic genes—Rh and rh—were concerned, Rh being dominant. When the husband's phenotype is Rh-positive and that of the wife Rh-negative the phenotype of the baby will depend upon whether the husband's genotype is RhRh or Rhrh. If the former, the infant's genotype will always be Rhrh and the phenotype therefore Rh-positive; if the latter, the phenotype will only be Rh-positive in 50% of the siblings. These considerations help to explain the different incidence of erythroblastosis in different families.

From this brief consideration of the circumstances in which the Rh factor has been shown to play an important part, it is clear that tests for Rh antigens and antibodies have considerable application in clinical medicine. This paper seeks to confirm many of the observations reported above and to present some new findings.

Sources of Test Serum

Test serum may be obtained from two sources. Either an animal, preferably the guinea-pig (Landsteiner and Wiener, 1941), may be immunized by being given a course of injections of blood from rhesus monkeys, or serum may be obtained from a human individual who has become immunized to the Rh antigen. In the first case the serum will always have to be absorbed, since it will contain other antibodies acting upon human erythrocytes. Furthermore, only certain animals produce satisfactory antibodies, and even from the good reactors only a small amount of serum will be obtained. The advantages of animal sera are simply that they can be produced at will and that their reactions are more uniform than those of human sera. By contrast, the advantages of using immune human sera for testing are that with good fortune a comparatively large amount of serum may be obtained with very little trouble. Unabsorbed human immune sera containing anti-Rh agglutinins can only be used for testing bloods of the same group or of group O, however, because, of course, they may also contain anti-A and anti-B agglutinins. These agglutinins either can be removed by absorption with appropriate human erythrocytes or, according to Wiener (1942), may be neutralized by the addition of saliva from individuals of groups A and B who are known to be "secretors."

---

* A report to the Medical Research Council from the S.W. London Blood Supply Depot.

† Throughout, the terms "Rh factor" and "Rh antigen" are used interchangeably, and the corresponding antibody is referred to as the Rh antibody, Rh agglutinin, or anti-Rh agglutinin.

In the present work a start was made by finding a serum, from a woman who had recently given birth to a baby with icterus gravis, which agglutinated the majority of bloods of its own group. The reactions were better at 37° C. than at 5° C. This serum was found to give reactions identical with those of a second similar serum that was obtained shortly afterwards, and the incidence of positive reactions produced by these sera suggested strongly that the agglutinins concerned were anti-Rh. Shortly afterwards, by the courtesy of the Rockefeller Institute, a sample of anti-Rh serum was sent to the Medical Research Council, and so it was possible to confirm that these human sera contained anti-Rh agglutinins. Through the kindness of Dr. Morgan of the Lister Institute we also had at our disposal some other samples of animal anti-rhesus serum obtained by the injection of guinea-pigs.

During the course of the work some 49 sera were found which contained demonstrable Rh antibodies. In accordance with the findings of other workers (Wiener and Peters; Landsteiner and Wiener; Levine, Burnham, Katzin, and Vogel) it was noted that the sera did not give entirely parallel reactions. The majority were observed to react with the same cells as those with which the animal sera reacted. A few sera, however, gave a higher percentage of negative reactions with a random selection of human bloods. Also, in occasional cases bloods were negative with one serum and positive with another. If human sera are used for testing, as they were in most cases in the present investigation, it certainly does not seem advisable to use less than 3 anti-Rh sera for testing (see also Davidsohn and Toharsky, 1942). At least 3, and often more, different sera were therefore used as a routine.

Test Cells

In agreement with the findings of Landsteiner and Wiener great differences were observed between the sensitivity of the cells of different Rh-positive individuals towards a given anti-Rh serum. Whereas with a given serum the cells of one individual may be completely agglutinated, those of another may show only a weak reaction. We have found that, although these differences are constant with any one serum, they differ from one serum to another, so that cells which react well with one serum may react poorly with another, while other cells may react poorly with the first serum but well with the second.

In examining a given serum suspected of containing anti-Rh agglutinins it is clearly advisable to test it against several different known Rh-positive bloods. Furthermore, in titrating the serum against Rh-positive cells it is essential to use the same cells for every estimation if accurate information is to be obtained about the changes in titre of the serum.

Technique of the Tests

Historical

In the reports of the first cases in which anti-Rh agglutinins were detected in human sera it was stated that the reactions were more pronounced at low temperatures and that no noticeable reaction at all occurred at 37° C. (Wiener and Peters). Accordingly, it was recommended that the mixture of cells and serum should be chilled. It was also suggested that the mixtures should be centrifuged before being examined microscopically for evidence of agglutination.

By contrast, sera described by Levine, Katzin, and Burnham (1941) were found to contain Rh agglutinins more active at 37° C. than at low temperatures. In a paper published a little later Wiener (1941) also recorded the finding of sera containing Rh agglutinins more active at 37° C. He stated that, despite the use of the centrifuge technique, no Rh agglutinins were found in 6 cases, in all of which there was a strong suspicion of their presence. At the end of the paper, however, Wiener refers to the fact that the tubes containing the mixtures of cells and serum from one of the cases showed a peculiar pattern of the sediment. In an article published soon afterwards (Landsteiner and Wiener, 1941) particular attention was drawn to this sediment pattern as a sign of a positive reaction. It was pointed out that after a mixture of cells and serum has been allowed to stand for some time the sediment at the bottom of the tube presents different appearances, according to whether or not agglutination has occurred. "Negatively reacting bloods [then] show a circular deposit with a smooth edge, while positive bloods have a wrinkled sediment with a serrated border or show a granular deposit."

It was pointed out that sometimes, in spite of a distinctly positive sediment picture, when the suspensions are examined microscopically the clumping may be quite weak. In our experience, rough treatment, such as sharp tapping of the tubes before the withdrawal of a sample for microscopical examination, can completely break up weak agglutination.

Using the cold centrifuge technique originally advocated by Wiener and Peters, we had several failures at first in attempting to demonstrate Rh antibodies. Later, by treating the mixtures more delicately and by working at a temperature of 37° C. instead of 5° C., it was possible to show that some of the sera examined did in fact contain Rh antibodies. Wiener (1942) has stated that the majority of Rh antibodies are more active at 37° C. than at 0° C., although in his opinion many of them are not much affected by alterations in temperature.

Procedure Recommended

(*a*) *Testing Unknown Cells.*—The following technique is very similar to that recommended by Landsteiner and Wiener (1941), although the importance of carrying out the tests at 37° C. when using human immune sera was first emphasized by Levine (1941).

A suspension of the cells to be tested is prepared by adding one small drop (0.02 c.cm.) of blood to 1 c.cm. of saline; the final concentration should be approximately 1 to 2% in terms of blood sediment. One volume of this suspension is placed with one volume of the test serum in a small tube, 7 mm. in diameter. As mentioned above, it is desirable to test cells with not less than 3 different sera. At the same time known Rh-positive and Rh-negative cells should be put up with the same sera to act as controls. The tubes should be left for at least one hour, and preferably for two hours, before being examined. For reasons discussed above, the tubes should be kept at 37° C. whenever possible, although with animal sera the reactions are just as satisfactory at room temperature (Wiener, 1942).

After the tubes have stood for one to two hours the sediment which has formed is examined, preferably with the help of a hand lens. The difference between typical negatives and positives has already been described, but it must be added that only the examination of a large series of sediments can make one familiar with all the possible appearances. When the sediments have been examined and the reactions have been scored, the sediment in each tube is gently mixed with its supernatant serum by means of a Pasteur pipette, and a little of the mixture is then withdrawn and spread on a slide, and examined microscopically. Usually, definite clumping is seen in blood taken from the tubes giving macroscopic positives. Occasionally, however, only very small agglutinates are seen despite a characteristically positive sediment, and, as we have said, harsh treatment of the mixtures in such cases sometimes completely abolishes the agglutination. Nevertheless we prefer to rely upon seeing agglutinates, macroscopically or microscopically, as a sign of a positive reaction, and simply to use the sediment pattern as a strong suggestion of the reaction to be expected. The danger of false negatives is of course reduced by the use of 3 different sera.

When the reactions are weak it may be very difficult to decide from the microscopical appearance whether the reaction is true agglutination or pseudo-agglutination (rouleaux-formation).

This is a further reason for the use of several different sera and for carrying out control tests with known Rh-positive and Rh-negative cells. Whenever sufficiently potent sera can be obtained it is desirable to add a volume of saline to the volume of serum and of cells in order to diminish rouleaux-formation.

(*b*) *Testing Unknown Sera.*—Sera suspected of containing Rh antibodies should be tested against at least 10 different group O bloods collected at random and also with not less than 2 known Rh-positive and 2 known Rh-negative bloods, using the technique described above. If the reactions are positive with the known Rh-positive bloods and negative with the known negatives, and if the serum reacts with the majority of the unknown group O bloods, it is practically certain that the atypical agglutinin is anti-Rh. It is advisable to test the serum with the cells of the individual from whom it came, to exclude the presence of abnormally powerful auto-agglutinins. If the latter are present they may be partially removed by leaving the serum in contact with its own clot at refrigerator temperature and then removing the serum while it is still cold.

(*c*) *Direct Matching Test.*—In any case in which there is a possibility that the recipient's serum contains Rh agglutinins it is most desirable to perform the direct matching test in such a way that reactions due to the presence of these agglutinins will be detected. As emphasized by Wiener (1942), Rh reactions are usually not detectable by an open slide method, and it is therefore necessary to set up the reactions in tubes as described above. We have tested the most potent anti-Rh sera that we have encountered against known Rh-positive cells, using the ordinary slide technique, and failed to detect any evidence of agglutination. It is therefore necessary to prepare a suspension of the donor's blood and mix it with the recipient's serum in a small tube as described above. Wherever possible the tube should be kept in an incubator for 1 to 2 hours; when an incubator is not available the tubes should be left to stand at room temperature for a similar period. Although it appears from Wiener's observations that occasional anti-Rh sera are more active at refrigerator temperature, it is our impression that such sera will prove to be very uncommon, and since testing at low temperatures introduces considerable additional difficulties it is suggested that in the present state of knowledge it is unnecessary to carry out a test at this temperature as well.

At the end of 1 to 2 hours the sediment at the bottom of the tube is examined, and the impression gained is confirmed by gently withdrawing a portion of the sediment and examining it microscopically. The least evidence of agglutination must be taken as a definite contraindication to the use of the particular donor.

When it is desirable to complete the test as rapidly as possible the tube containing the mixture of cells and serum may be centrifuged slowly at the end of 30 minutes (500 r.p.m. for one minute) (Levine, 1941). The tube is then gently shaken and the contents examined. We do not, however, consider this technique to be as reliable as that already described.

It may be emphasized that Rh agglutinins occurring in human sera are immune bodies and that therefore their titre varies considerably, according to the time which has elapsed since their stimulation by the Rh antigen. Following the transfusion of Rh-positive blood, for instance, there may be a negative phase in which the titre is low and it may be impossible to demonstrate Rh antibodies at all. During the next few days the strength of the antibody increases, and reaches a peak some 7 to 21 days after the transfusion. Thereafter the titre falls slowly.

Little evidence has so far been collected about the period of gestation at which Rh antibodies occur in cases where their formation is stimulated. We have, however, noted that the titre is low soon after delivery and that it rises to a maximum between 7 and 21 days later. The antibody may have practically disappeared in a few months or may still be detectable 5 years later, as in one of our cases.

Results

Random Samples of the Population Examined

A random sample of blood donors (all white; groups A + O) was tested with several human anti-Rh sera. All the sera used for these tests were considered to give similar reactions to the guinea-pig sera, and presumably correspond to the standard type described by Wiener (1942) or to the "No. 1 in our series" of Davidsohn and Toharsky (1942).

Of 1,610 cases, 1,371 (85.15%) were found to be Rh-positive and 239 (14.85%) Rh-negative. These figures correspond closely with those recently quoted by Wiener (1942) (of 777 persons examined, 14.4% were found to be Rh-negative)

Mothers of Infants affected with Erythroblastosis

Diamond, Blackfan, and Baty (1932) first suggested that universal oedema of the foetus, icterus gravis neonatorum, and anaemia of the newborn were all manifestations of the same underlying disease process and could be conveniently grouped together and known as "erythroblastosis foetalis."

Before mentioning the findings in a group of these cases, attention is drawn to the difficulty that is sometimes encountered in diagnosing erythroblastosis in the infant. Clinicians have stated that no line can be drawn between mild "icterus gravis" and physiological jaundice of the newborn (Hawksley and Lightwood, 1934). Certainly, if the passage of immune incompatible agglutinins across the placenta is accepted as the main causative factor in this disease, all degrees of severity will be expected.

According to Diamond, Blackfan, and Baty, the features which enable jaundice associated with erythroblastosis to be differentiated from "physiological jaundice" are its earlier appearance and greater duration, and the associated features of an excess of erythroblasts in the peripheral blood at birth and their persistence for many days or weeks after delivery, together with anaemia, splenomegaly, and hepatomegaly. However, even when these diagnostic criteria are considered there may still be doubt as to the diagnosis because great variations in all these features are encountered. In making observations upon the serological findings in the mothers of infants with erythroblastosis it has been thought preferable to keep to classical cases of the disease, and this we have done. Nevertheless, attention will be drawn to a group of jaundiced babies who possibly exhibit a mild form of the condition.

We tested 48 mothers whose babies had definite erythroblastosis; 46 of these were found to be Rh-negative, and in 44 cases Rh antibodies were present. In all 48 cases the infant was Rh-positive. In the 4 cases in which no Rh antibody was found in the mother's serum, other group differences were evident—e.g., the mother belonged to group O and the foetus to group A. The difference was always such that the mother's serum contained an agglutinin incompatible with the infant's erythrocytes. The possible relevance of this finding is discussed below. In 9 cases in which the mother's serum contained Rh antibodies the infant's serum was examined for the presence of these antibodies. In 8 cases in which the infant was 3 to 10 days old at the time of examination no antibodies were detected. In the ninth case, however, in which the sera of identical twins were examined within 24 hours of birth, definite Rh agglutinins were found in both. This is believed to be the first recorded instance of this finding.

The Rh agglutinins in the mother's serum were titrated at room temperature and at 37° C. in every case, using a standard technique (Taylor and Ikin, 1939), but the mixtures were handled more delicately than usual. In most instances the agglutinins were titrated at intervals after delivery, and these results will be reported separately. It may be useful, however, to mention that out of 41 cases examined within a month after delivery very high titres (over 512) were found in 3, moderate titres were found in 19, and very low titres (under 8) were found in 19 cases. These figures refer to the maximum titre recorded in each individual case; in the majority of instances the figures probably approach the maximum titre reached, but they do not necessarily do so in all cases.

Cases of "Physiological" Jaundice

As mentioned, this does not seem to be a sharply defined group. For the present purpose any baby developing jaundice has been included provided that there were none of the classical features of erythroblastosis described above and provided that there was reasonable evidence that syphilis, sepsis, or congenital obliteration of the bile ducts was not responsible for the jaundice. Tests were made in 24 mothers; 3 were Rh-negative. In these cases the baby was found to be

Rh-positive and the mother's serum contained an Rh antibody. Moreover, in one of these cases the mother had previously given birth to an infant affected with icterus gravis neonatorum. This finding suggests that certain cases usually diagnosed as physiological jaundice would be more properly regarded as mild cases of erythroblastosis. The supposition that the aetiology of some cases of mild jaundice of the newborn is connected with the passage of incompatible agglutinins across the placenta receives further support from the findings in the other mothers and infants investigated. In these the incidence of cases in which the mother's serum was incompatible with the infant's erythrocytes (due to the presence of anti-A or anti-B agglutinins) was considerably higher than the expected incidence in a random sample of mothers and infants.

(*The concluding part, with a list of references, will appear in next week's issue*)

TREATMENT OF SHOCK BY DIRECT ACTION ON THE VEGETATIVE NERVOUS CENTRES*

BY

LENA C. STERN, M.D.

Professor of Physiology, Second Moscow State Medical Institute

The Mechanism of Traumatic Shock

Efforts to produce shock experimentally play an important part in the elucidation of the mechanism of traumatic shock. The criteria of shock conditions in all these experiments were: (1) sudden and persistent fall in blood pressure, with a rapid and feeble pulse, (2) shallow breathing, (3) the absence of reaction on irritation, (4) lowering of the temperature. All this points to a disturbance of the vegetative nervous system, particularly the sympathetic, which in itself leads to a diminution of volume of the circulating blood, due to the accumulation of blood in the blood depots and diminution in the liquid part of the blood from plasmorrhoea. This disturbance of the vegetative nervous system is also a cause of chemical changes which characterize the course of shock (appearance of acidosis, diminution of glucose, etc.). This work also showed that with the weakening of the sympathetic nervous system there is a stimulation of the parasympathetic system which shows itself by a number of inhibitive effects.

Experiments made by us and our colleagues (Rosin, Chvoles) have proved that sensitivity, especially to pain, plays an important part in the development of shock. They showed that irritation of the skin by an induction current for 2 to 6 hours causes shock, whereas with preliminary anaesthetizing of the skin with novocain much longer electrical stimulation is without effect. Given the same conditions, shock is most easily produced by irritation of the skin on the inner surface of the thigh, the peritoneum, and the periosteum, whereas irritation of the dura even for as long as 8 to 12 hours does not cause shock. The rhythm of irritation is important, shock usually appearing much more quickly when the rhythm is quicker.

The significance of the preceding conditions for the development of shock in man has been proved by clinical observations. Excessive tiredness, prolonged insomnia, insufficient nourishment, fear, exposure, loss of blood, and, not least, painful irritations, lead, after transient overstimulation of the sympathetic nervous system, to its exhaustion and thus facilitate shock. The results of these experiments show that shock is caused, apart from loss of blood, by a whole complex of circumstances connected with a definite condition of the nervous centres. Only when all these conditions are present does shock develop. In clinical studies of shock, attention has been mainly directed to the functional state of the peripheral organs, such as the cardiovascular and respiratory organs. A more detailed analysis, however, has shown that all these cardinal changes, including the changes in metabolism and in the physical and chemical state of the blood and the tissues, are not actually specific to shock. In fact, similar changes, such as a fall in blood pressure, diminished nervous reactions, etc., can be caused by a depression of the sympathetic nervous system such as occurs also in other pathological states. All these changes form a syndrome which characterizes shock and shock-like conditions and can be caused by action on the vegetative centres; this points to the important part played by the central nervous system in the production of shock. It therefore follows that in order to be able to understand the mechanism of shock and to apply useful therapy and prophylaxis one must concentrate on the functional conditions of the nervous centres, on their metabolism, and, in conjunction with this, on the character of the cerebrospinal fluid—i.e., their immediate nourishing medium.

Function of Cerebrospinal Fluid

The importance of the cerebrospinal fluid to the functioning of the nervous centres has been shown by observations in laboratories and clinics for many years. These observations have proved that the cerebrospinal fluid (taken in its broad sense as the fluid which fills not only the ventricles of the brain and the subarachnoid space, but the whole of the perivascular and pericellular spaces of the brain tissue) is the immediate nourishing medium of the central nervous system. The chemical composition, as well as the physical, chemical, and biological character, of the cerebrospinal fluid mainly depends on, and is determined by, a special mechanism—the so-called haemato-encephalic barrier. The anatomical substratum of this barrier is, apart from the vascular plexus, the capillaries and precapillaries of the brain, in the first place their endothelium. The haemato-encephalic barrier has a great selective capacity, on account of which not all substances which normally circulate in the blood, or get there accidentally, pass from the blood stream into the c.s.f. There takes place "a certain choice" as the result of which a relative constancy of the composition of the c.s.f. is maintained, and there is a certain independence of possible changes in the consistency and quality of the blood.

It has been shown that not only the introduction of abnormal substances from the blood into the c.s.f., but even a simple disturbance of interrelations between the normally existing substances in the c.s.f., such as between certain electrolytes, causes a more or less severe reaction in the nervous centres which sometimes leads to the death of the animal. In certain cases we were able to notice that definite changes in the c.s.f. are accompanied by some features which resemble the complex of symptoms characteristic of shock and similar states. This particularly applies to the ions of Ca and K. It was shown that change in the concentration of these ions in the c.s.f., leading to a change in the coefficient K/Ca, has a very strong influence on the condition of the central nervous system, particularly on the vegetative centres. For example, the introduction of minimum doses of Ca salts directly into the c.s.f., especially into the ventricles, brings about in the animal a condition of severe depression, whereas the introduction of minimum doses of K salts produces pronounced excitement. This suggests that the direct cause of the change in the functional condition of the cerebrospinal system may be a corresponding change in the composition of the c.s.f. Comparing the occurrence in shock of changes in the different physiological systems, particularly in the cardiovascular and respiratory systems, with the action which causes a stimulation of the vegetative nervous system, we conclude that the sympathetic and parasympathetic nervous centres play the most important part in the production of shock. The cause of changes in the vegetative nervous centres may be strong irritation coming from the periphery. The intensity of effect brought about by such irritations depends on the preceding condition of the vegetative centres (their greater or lesser excitability and reactivity), which in itself is closely connected with the chemical composition of the c.s.f.

The possibility of varying the reaction of the sympathetic and parasympathetic centres by introducing into the cerebrospinal canal certain substances such as K salts and Ca salts points to the influence of the electrolytic composition of the c.s.f. on the condition and activity of the vegetative nervous system. Diminished tone of the sympathetic centres causes those disturbances of function characteristic of shock, and especially of the haemodynamics, the disturbance of which is quite sufficient to bring about in different physiological systems those changes which characterize shock. It is therefore understandable that all efforts to combat the signs of shock are mostly directed to the re-establishment of circulation and the normal action of the cardiovascular system.

---

* Translated by Dr H. W. Swann.

Failure of Shock Therapy

However, the ordinary methods of fighting shock generally do not give positive results, because they do not influence the condition of the central nervous system. These negative results are explained to a great extent by the presence of the haemato-encephalic barrier.

As regards certain medicinal substances, it has been noted that, introduced into the circulation, they have no effect on the central nervous system, whereas the introduction of minimal quantities of the same substances directly into the cerebrospinal canal, particularly into the ventricles, often has a marked effect. The conclusion, therefore, is that in order to obtain a positive effect one should introduce the substance intrathecally. The action of a substance admitted into the general circulation differs from the action of the same substance introduced straight into the c.s.f. This applies particularly to those substances which are normally present in the c.s.f. and the blood, such as K and Ca salts and some hormones. Many experiments have proved that there is an antagonism between the central and peripheral parts of the vegetative nervous system as regards their reaction to the same substance. This antagonism more or less explains the absence of a positive anti-shock action of the medicinal substance when introduced straight into the circulation. Actually, if these substances do penetrate into the central nervous system, particularly the vegetative centres, they may produce an opposite effect and thereby neutralize the immediate action which they have produced on the peripheral vegetative organs. It follows, therefore, that in order to understand the action of a given substance one must take into consideration not only the permeability of the haemato-encephalic barrier for this particular substance, but also the fact that the substance which easily passes through the haemato-encephalic barrier into the c.s.f. may, on contact with the vegetative centres, cause an action which is opposite to the one on the peripheral organs. There is, therefore, an interference, and the final effect may be negligible or even opposite to the one expected. To produce a direct action on the vegetative nervous centres one must administer the substance directly into the c.s.f.

One must add that a positive effect can be obtained only in cases in which the given substance is introduced into the ventricles of the brain, whereas the introduction of the substance into the subdural or subarachnoid spaces is usually without effect because it passes rapidly from the c.s.f. into the blood stream and does not come into contact with the nervous centres.

Intraventricular Injection of K Salts

Laboratory experiments (Chvoles) have shown that in many cases of experimental traumatic shock the direct injection into the c.s.f. of a solution of K salts gave a positive result. In most of the experiments the signs of shock disappeared very quickly, the blood pressure rose rapidly to normal, the rhythm of respiration became normal, as also the reactivity and excitability of the animal.

It is interesting to note that in those cases in which trauma was accompanied by a severe loss of blood (up to 50%) the introduction of potassium phosphate into the c.s.f. without a preliminary blood transfusion brought the animal out of shock, whereas in control experiments the introduction of a physiological solution as well as a transfusion of blood had no effect. It appears, therefore, that under the influence of increased excitability of the sympathetic centres there is a mobilization of the blood from the depots and simultaneously a transference of fluid from the tissues into the blood, as a result of which the volume of the circulating blood is increased.

The best results have been obtained by injecting potassium phosphate directly into the lateral ventricles or into the cisterna magna, provided that definite rules are followed. If these rules are not observed, the injected fluid often does not reach the cerebral ventricles, but, following the normal flow of the c.s.f., passes into the subarachnoid space without reaching the vegetative centres. The introduction of the fluid into the subarachnoid space does not produce the necessary effect, because it passes into the blood stream very quickly without coming into contact with the nervous centres. It can now be positively stated that by fulfilling the necessary conditions as regards concentration, temperature, and reaction of the solution of potassium phosphate, as well as the rules of technique of its introduction into the cerebrospinal canal (i.e., the ventricles), a definite effect can as a rule be obtained. It is obvious that a positive action of potassium phosphate on the vegetative nervous centres is possible only if the centres have still retained the ability to react. Completely exhausted vegetative centres which have lost their reactivity cannot be re-established by this method.

Taking into consideration the fact that the introduction of potassium phosphate into the cerebrospinal fluid increases the tone of the sympathetic centres, its use is indicated in those cases in which symptoms of weakened tone are present. Irrespective of whether we deal with shock or a shock-like condition, we cannot possibly expect any useful effect in cases in which there is an anatomical injury to the vegetative centres. An effect can be expected only in a purely functional disturbance of the vegetative nervous system.

The time factor is of great importance. One obtains the best results in cases when the potassium phosphate is introduced into the ventricles of the brain within a short time after the appearance of shock. This applies not only to traumatic shock but also to anaphylactic, peptone, and histamine shocks. This can be explained by the fact that the exhaustion of the vegetative centres gradually increases, and when it reaches a certain stage the possibility of stimulating them by any method disappears.

The results obtained by laboratory methods have been fully corroborated by clinical experience and at the front. To obtain a positive effect 1 c.cm. of a solution of potassium phosphate in a concentration of 1/6 gramme-molecule, with pH of 7.6, was found best. Introduction of potassium phosphate into the lateral ventricles not only increases the concentration of potassium but also diminishes the concentration of the Ca ions, which leads to a considerable increase in the coefficient of the K/Ca ions. When the potassium phosphate is injected, one must remember the necessity for rapid penetration into the ventricles so that direct contact may be obtained with the vegetative nervous centres. Laboratory experiments, as well as clinical observations, have shown the importance of the preceding condition of the sick or wounded, particularly the increased excitability of the nervous system in the development of shock. In prophylaxis it is rational to counteract the increased excitability so as to prevent exhaustion, which causes shock, by giving sedatives, and blood transfusion when there is loss of blood. To prevent a possible relapse this prophylaxis can be successfully applied also in the initial stages of shock, as well as after the shock has disappeared. The first condition for preventing a repetition of shock syndrome in traumatic shock is the removal of the direct cause of shock, particularly the source of painful sensations, as, for example, by local anaesthesia. Fluid can be introduced into the ventricles of the brain by way of cisternal puncture. The following rules must be observed.

Technique of Cisternal Injection

The patient must be in a horizontal position (preferably on his left side); the head must be lower than the body and bent on to the chest; the lower limbs must be flexed (a position similar to Trendelenburg's). The landmarks are the external occipital protuberance and the first cervical spinous process. These landmarks are felt on the back of the head, which has been shaved and thoroughly disinfected. One fixes with a finger the skin between these two points and inserts the needle exactly in the midline at the level of the external auditory meatus. Sliding along the occipital bone one reaches the atlantoid membrane. The moment this membrane is perforated one hears a crackling sound. For this puncture one may use a graduated cisternal needle or an ordinary lumbar puncture needle. As a preliminary measure one estimates the length which corresponds with the depth of the puncture (from 4 to 5 cm.). The criterion that the needle has penetrated into the cisterna magna is the appearance of translucent c.s.f., which escapes from the needle after removal of the stylet. On account of weak pressure in shock conditions the c.s.f. very often does not appear spontaneously and has to be drawn out by a syringe. After 1 to 2 c.cm. of the c.s.f. have been withdrawn with a syringe, 1 c.cm. of the solution of potassium phosphate, which has been warmed to body temperature, is injected with a syringe under a definite pressure, so that it penetrates into the ventricles. This method of treatment is very easy and can be applied at the front. The preparation of the potassium phosphate solution is not complicated, but must be done very carefully. The glass of the ampoules must be neutral. The solution is a mixture of the monometallic and bimetallic potassium phosphate (concentration 1/6 gramme-molecule), and can be prepared either from these salts (K_2HPO_4 and KH_2PO_4) or by adding the orthophosphoric acid to a solution of corrosive potassium up to pH 7.6.

As a rule the effect of this injection takes place in 1 to 2 minutes or even sooner (i.e., in the first place the blood pressure rises and the respiration becomes deeper). The absence of effect within a few minutes is generally due to the fact that the fluid has not reached the ventricles, as a result of the incorrect direction of the needle or of insufficient pressure. In these cases one must repeat the operation. When toxaemia is threatening—i.e., when toxic substances which form in the injured tissues enter the blood—the further formation of these substances must be stopped by excising the injured parts where possible; positive results, which are obtained by the direct action of potassium phosphate on sympathetic nervous centres, do not exclude the possibility of the appearance of toxaemic shock later on

Conclusions

1. In the last phase of traumatic shock there is first of all a considerable fall in the tone of the sympathetic nervous system and a partial rise in the tone of the parasympathetic nervous system.

2. The most effective way of combating traumatic shock in its later phase is to raise the tone of the sympathetic centres by direct action on the vegetative centres; potassium phosphate simultaneously raises the tone of the sympathetic centres and lowers the tone of the parasympathetic.

3. By direct action on the nervous centres the ionic potassium causes an excitability of the sympathetic nervous centres, whereas the ionic phosphates, by concentrating the ionized Ca, cause a diminution of the tone of the parasympathetic nervous centres.

4. A direct introduction of potassium phosphate into the cerebrospinal canal contributes to a quicker action of this substance on the nervous centres and at the same time obviates the possibility of its opposite effect on the peripheral part of the vegetative nervous system.

5. The use of potassium phosphate as an anti-shock remedy is indicated in all those cases in which there is a diminution of the tone of the sympathetic nervous centres, such as a fall of the blood pressure, a lowering of cardiac activity and respiration, diminution of excitability, reactivity, etc.

6. Potassium phosphate must never be used in cases in which there is increased excitability of the sympathetic nervous centres, such as sometimes occurs in the first stage of shock.

7. If haemorrhage is present it must be arrested by all available means, because the considerable rise of the blood pressure through the introduction of potassium phosphate will definitely increase haemorrhage.

8. To avoid a repetition of shock it is necessary after the introduction of potassium phosphate to remove the actual cause of shock, in particular painful stimuli.

9. To ensure the direct action on the vegetative nervous centres, which are situated in the ventricles of the brain, potassium phosphate must be introduced directly into the ventricles. This is done by means of cisternal puncture. The fluid must be introduced with a definite pressure and the direction of the needle must be correct. The position of the patient must be horizontal, preferably on the left side, and the head must be lower than the body.

10. One must act quickly, without loss of time, so as to avoid a complete exhaustion of the vegetative centres.

11. The introduction of potassium phosphate does not exclude all the other measures against shock, especially blood or plasma transfusion.

12. Blood transfusion must be done in all cases where there is marked loss of blood. In other cases a blood transfusion is not absolutely necessary.

RECENT TRENDS OF SOME INFECTIOUS DISEASES

BY

W. J. MARTIN, Ph.D.

(Of the Medical Research Council Statistical Staff)
London School of Hygiene and Tropical Medicine

The results obtained by the introduction of new methods of treatment in certain types of infectious diseases have in hospital experience been almost dramatic. It seemed worth while to find whether any change could be shown in the number of deaths for the whole country from the numerically more important causes for which control has been attempted. The estimated saving in lives following the introduction of new methods forms an interesting speculation. The death rates cannot be used as a statistical index, since the populations at risk in 1940 and 1941 are not definitely known, so the ratio of deaths to notifications has been adopted.

Cerebrospinal Fever

The employment of chemotherapy in cerebrospinal fever has resulted in a very large decline in the fatality rate from this cause. A large increase in incidence of cerebrospinal fever occurred after the outbreak of war, an experience similar to that of 1914-18. The statistics for recent years in England and Wales are:

Year	Deaths	Notifications	Deaths per 100 Notifications
1934 ..	729	1,080	68
1935 ..	617	865	71
1936 ..	635	967	66
1937 ..	698	1,113	63
Average of 1934–7	670	1,006	67
1938	652	1,258	52
1939	517	1,500	34
1940	2,584	12,767	20
1941 ..	2,163	11,073	20

If the average of the years 1934-7 is taken as representing the endemic level immediately before the general use of sulphapyridine, it will be seen that a great improvement has been effected. The fatality rate was halved in 1939, and in 1940 and 1941 it was less than one-third of the average value. On the basis of the average fatality rate of 66.60% during 1934-7, the expected number of deaths in the three years 1939-41 would have been 16,876. The number actually registered was 5,264, or 11,612 fewer than expected. This is probably an over-estimate, since in a period when a disease is prevalent fewer mild cases are missed and there tends to be a greater proportion of wrongly diagnosed cases than in non-epidemic periods—factors that produce a decrease in the fatality rate. The most recent pre-war epidemic occurred during 1931-3, when 5,919 notifications with 3,595 deaths were reported, giving a fatality rate of 60.74%. The expected deaths in 1939-41 on the basis of this fatality rate would be 15,392 —i.e., 10,128 in excess of the observed. An objection that could be raised to this comparison is that the conditions of life were vastly different in the two periods. To obtain approximately similar conditions of life—the aggregation of large sections of the population—it is necessary to go back to the last war. During the epidemic of 1915-17 there were 5,222 deaths and 8,068 notifications, yielding a fatality rate of 64.72%. Taking this rate as a standard, the expected deaths in 1939-41 would have numbered 16,400, or 11,136 more than were recorded.

It seems reasonable to suggest that as a consequence of the discovery and adoption of treatment by sulphapyridine about 10,000 lives were saved during 1939-41.

Pneumonia

The response of cases of pneumonia, particularly lobar pneumonia, to treatment with sulphapyridine has been very successful, and large declines in hospital mortality have been recorded. The effect of this treatment on the mortality of the whole country cannot be measured directly by means of the case-fatality rate, since we have no knowledge of the number of cases. Many factors influence the trend of the mortality from pneumonia, and consequently large fluctuations occur in the annual rates. These variations prevent a straight comparison being made between the number of deaths occurring in each year. The incidence of bronchitis has been used as a criterion to test whether the years in question were favourable or not to respiratory diseases. Unfortunately the deaths from lobar pneumonia are not available for 1940-1; the only data available are for all forms of the disease at all ages. There has been a change in the method of classification of causes of death in these years: previous to 1940 the Registrar-General gave priority to certain causes, and now he accepts the order of death stated by the medical attendant on the certificate. The deaths for 1938 and 1939 can be ascertained by both methods, and a comparison shows that the new classification slightly increases the total of pneumonia deaths and doubles those from bronchitis. The factors for reducing the totals to the old classification are 0.9466 for pneumonia and 0.5007 for bronchitis. Applying these corrections to the years 1940 and 1941, we obtain the following:

	All Forms of Pneumonia		Bronchitis	
	Deaths	Percentage of Average of 1934–7	Deaths	Percentage of Average of 1934–7
Average 1934–7 ..	28,281	100	17,048	100
1938	25,945	92	13,273	78
1939	22,207	79	15,463	91
1940	27,636	98	23,179	136
1941	25,006	88	17,050	100

The deaths from bronchitis suggest that a particularly severe respiratory mortality was experienced in 1940. The difference between the percentage value for pneumonia and bronchitis was 12 in 1939 and 1941, but the difference of the percentages was much larger—38—in 1940. This difference of 12% might be used as an estimate of the effect of the new therapy on the mortality in 1939 and 1941, but the value for 1940—38%—would be an overstatement, since bronchitis tends to fluctuate more than pneumonia. This can be illustrated by taking the deaths for the previous 10 years and expressing them as a percentage of the mean number of deaths. The deviations then found are:

	1928	1929	1930	1931	1932	1933	1934	1935	1936	1937
Pneumonia ..	0·4	41·9	−10·2	8·7	−4·3	−2·7	−7·3	−13·3	−8·8	−4·4
Bronchitis ..	11·0	58·1	−7·5	19·2	−3·7	−0·2	−19·7	−25·3	−16·6	−15.3

Although there has been an undoubted decrease in the mortality rate from pneumonia, an estimation of its extent is rather speculative. It seems probable that the deaths would have been 10% higher, and if we can accept this as a not too optimistic approximation then 7,500 lives were saved during 1939-41.

The deaths from lobar and other forms of pneumonia are differentiated in the returns for Scotland. The statistics for recent years in Scotland were:

	Lobar Pneumonia		Other Forms of Pneumonia		Bronchitis	
	Deaths	Percentage of Average of 1934–7	Deaths	Percentage of Average of 1934–7	Deaths	Percentage of Average of 1934–7
Average 1934–7	1,441	100	3,256	100	3,104	100
1938	1,188	82	2,644	81	2,462	79
1939	782	54	2,167	67	2,653	85
1940	873	61	3,367	103	4,317	139
1941	873	61	2,699	83	3,091	100

The experience of Scotland is very similar to that of England and Wales if the trend of the deaths from bronchitis is used as a standard of comparison of respiratory mortality. It is evident that there has been a reduction in mortality from pneumonia, with a very large decrease in lobar pneumonia. In 1940 the deaths from bronchitis were 39% above the mean value, while the deaths from lobar pneumonia were 39% below the average and the deaths from other forms of pneumonia were only 3% in excess of the mean.

The reduction in the number of deaths from pneumonia was relatively greater in Scotland than in England and Wales. The mean annual number of deaths during 1939-41, expressed as a percentage of the mean of 1934-7, was for all forms of pneumonia 88% in England and Wales and 76% in Scotland, while the values for bronchitis were almost the same—109% in England and Wales and 108% in Scotland.

Puerperal Sepsis

Puerperal sepsis forms numerically the most important component of maternal mortality. In the 10 years preceding the war 40% of the total maternal deaths were attributed to this cause. The continuity of the statistics was broken in 1940 by the adoption of a new classification: beside the modification in the method of classification, described in the paragraph on pneumonia, several causes were added to puerperal sepsis. The statistics for recent years, using the 1940 mortality classification, were:

	Total Births	Puerperal Pyrexia		Puerperal Sepsis	
		No. of Notifications	Rate per 10,000 Births	No. of Deaths	Rate per 10,000 Births
1931 ..	659,014	8,085	123	1,208	18
1932 ..	640,443	7,567	118	1,162	18
1933 ..	605,497	7,899	130	1,213	20
1934 ..	622,851	8,431	135	1,350	22
1935 ..	624,191	8,142	130	1,165	19
1936 ..	630,337	8,267	131	1,035	16
1937 ..	635,363	8,849	139	731	12
1938 ..	645,933	9,307	144	682	11
1939 ..	643,661	9,245	144	649	10
1940 ..	629,760	7,582	120	478	8
1941 ..	608,130	7,352	121	499	8

Since the number of cases of sepsis is unknown the best measure of the trend of the mortality is to relate the deaths to the births. Although the case rate cannot be found, the incidence of puerperal pyrexia suggests that the prevalence of sepsis at the beginning and that at the end of the period were similar, with possibly an increase in the intervening years. The above figures show that the mortality from puerperal sepsis has declined considerably and the rate during 1940-1 had decreased to less than a half of the value of a few years earlier.

Measles

A considerable decrease in mortality from measles has occurred during the past 20 years, but this disease differs from those previously discussed, as, although there has been steady progress in the control of measles, especially in the large towns, no sharp line can be drawn dividing the period into pre-treatment and post-treatment years. The number of deaths in England and Wales in two-year periods, to eliminate the fluctuations in the annual deaths due to the periodicity of measles, were:

Period	Deaths	Period	Deaths
1922–3	11,010	1932–3	5,348
1924–5	10,171	1934–5	5,114
1926–7	7,205	1936–7	3,802
1928–9	7,690	1938–9	1,942
1930–1	7,476	1940–1	2,129

Although the character of the attack and the severity of the accompanying complications vary from epidemic to epidemic there has been an almost progressive decline in the number of deaths. Serum prophylactics have been employed during the past decade, and special therapeutic measures—e.g., oxygen therapy—have probably influenced the trend of mortality. Other important contributing factors were the improved standards of nutrition and hygienic conditions and, in London, a greater proportion of admissions to hospital. A lowering of the virulence of the causative organism may also have had an effect. It is impossible to assess the relative importance of these various causes of the decline in mortality.

A comparison of case fatalities cannot be made, since measles has been notifiable only since the start of the war.

The population at ages 0–15 has fallen by almost one-fifth during the past 20 years, and this must be taken into account when estimating the change in mortality. If the deaths are related to the average population aged 0–15 in 1922-5 and this factor is applied to the estimated population at 0–15 in 1940-1 (obtained by extrapolating a straight line fitted to the population at 0–15 of 1935-9) the resulting expected deaths for 1940-1 would be 8,722—i.e., 6,593 in excess of those observed.

We may conclude that the sum of the various factors operating towards a decline has resulted in a reduction of childhood mortality from measles of about three-quarters of what it was 20 years ago.

REDUCTION OF OLD-STANDING DISLOCATION OF THE KNEE-JOINT

BY

F. P. FITZGERALD, M.B., B.Ch., F.R.C.S.I.

Orthopaedic Surgeon to St. Anthony's Hospital, Cheam, and Wellhouse Hospital, Barnet (E.M.S.)

There are two main indications for attempting reduction of a long-standing dislocation of the knee-joint: first, to relieve pain; secondly, to overcome shortening as a preliminary to an arthrodesis, or excision of the joint. Forcible manipulation for such cases is usually contraindicated, and wedge plasters are obviously ineffective. The case here described was treated by the method devised by Hamilton Russell (1924) for the treatment of fractures of the shaft of the femur. This was slightly modified, skeletal traction being used instead of strapping extension.

Case Report

History.—A man aged 56 had suffered from rheumatoid arthritis "for years." He had been confined to bed for over two years and, according to his doctor, the duration of the dislocation was about 18 months. On examination the right knee was obviously dislocated. It was flexed to 140 degrees, with the leg externally rotated through 50 degrees (Fig. 1). Under an anaesthetic there were about 10 degrees of movement present.

Treatment.—The hip was placed on an adjustable Braun splint, so that traction could be exerted in the line of the deformity (Fig. 2). Skeletal traction was applied through the os calcis. This was used instead of strapping so that the external rotation could be controlled. A sling was passed under the knee and attached to a cord which passed over a pulley (*a*) on a Balkan beam. Thence it was continued to another pulley (*b*) on the vertical limb of the Balkan beam at the level of the leg. A third pulley was fixed to the Böhler stirrup on the os calcis nail (*c*), and a fourth (*d*) tied to the upright just below *b*. The cord was then threaded over these and finally attached to a weight of 7 lb. The foot of the bed was elevated.

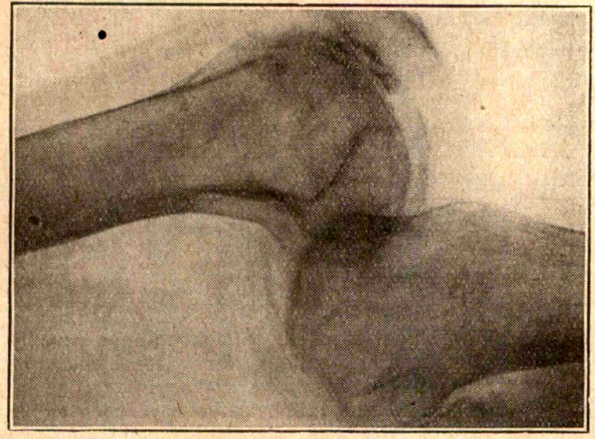

FIG. 1.—Note the clear view of the tibio-fibular joint due to the marked external rotation of the tibia.

A cord was fixed from the outer side of the nail to a weight suspended by a pulley (*e*) on the horizontal limb of the Balkan beam to control external rotation.

Three weeks later a radiograph was taken, and it showed that the dislocation had been reduced (Fig. 3). During this time the patient did not complain of any undue discomfort. As the knee was on the adjustable type of Braun splint (Fig. 4), it was possible to lower its horizontal position and thus gradually to extend the knee. By doing this and altering the line of pull accordingly, the limb could be straightened completely. This took approximately 7 weeks.

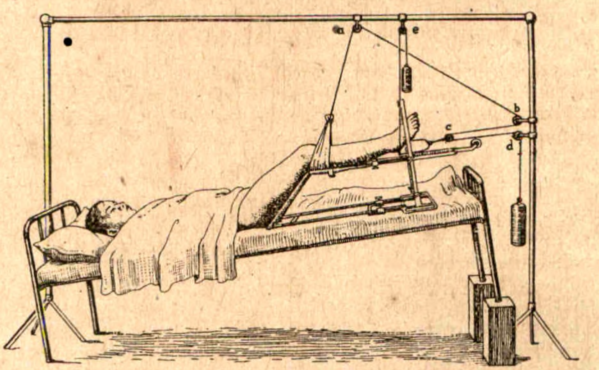

FIG. 2.—The traction under the knee pulls the head of the tibia forwards. The cord attached to the nail and passing over the pulley (*e*) helps to rectify the external rotation. The adjustable splint has been flexed to fit the contracted knee.

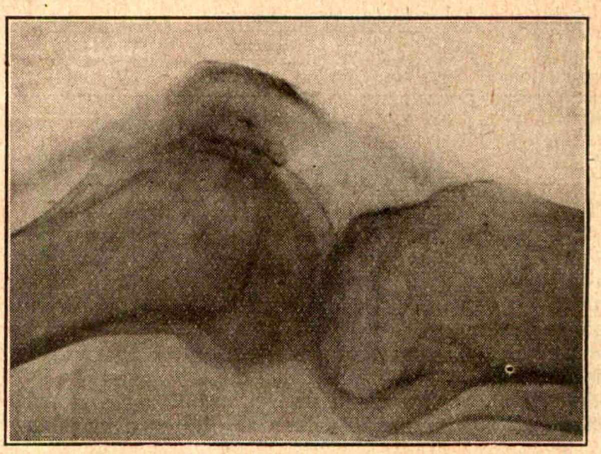

FIG. 3.—The dislocation has been reduced.

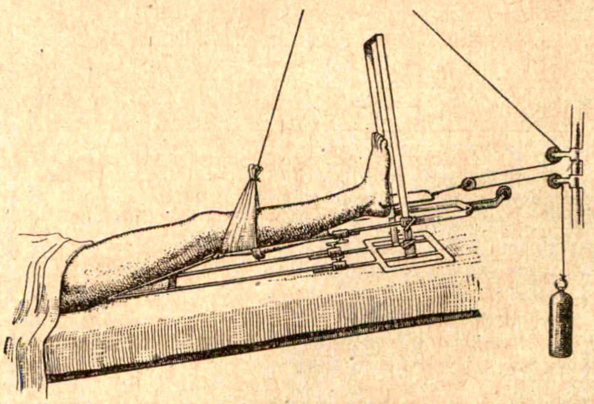

FIG. 4.—The external rotation has been corrected and the splint has been lowered so that the knee is almost straight.

Summary

A simple method of reducing an old dislocation of the knee-joint is described. The ease with which the reduction was achieved makes it possible that this case was exceptional; but the simplicity of the manœuvre would seem to warrant a trial in such cases.

Medical Memoranda

A Pencil in the Urinary Bladder

There are many accounts in the literature of an endless variety of foreign bodies in the urinary bladder, but I could not find another exactly comparable to the present case, and it therefore seems worth placing on record.

CASE HISTORY

A married man aged 28 was admitted to hospital complaining that he had a pencil in his bladder. He was accompanied by his doctor, who gave the history that the patient had introduced the foreign body the previous night.

On examination he was seen to be a well-developed man. His temperature was 98.6°, pulse 80, and respirations 20. He had only slight pain. He was able to pass water, but micturition was accompanied by pain, especially at the end of the act. On occasion there was obvious blood in the urine. The frequency of micturition was every 4 to 5 hours during the day and night. The stream was only a little impaired. The bladder was not distended. The end of the pencil was palpable in the perineum, projecting from the region of the bulb of the urethra and lying close under the skin. There was no extravasation of urine. By deep palpation above the symphysis pubis the pencil could be felt bimanually and movement conveyed to its extremity. There was no discharge of blood from the urethral orifice, but the latter showed signs of having been stretched, probably on a number of previous occasions. A radiograph (Fig. 1) showed the pencil lying vertically in the pelvis behind the symphysis pubis and projecting into the perineum.

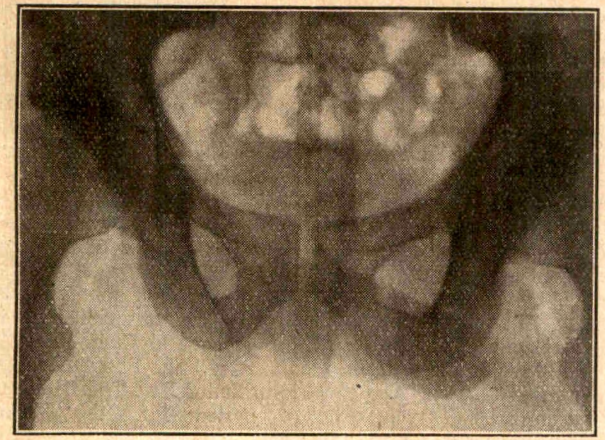

FIG. 1.—Radiograph showing position of the foreign body.

Cystoscopy was performed under general anaesthesia. The cystoscope on reaching the bulb of the urethra touched the pencil but slipped through the prostatic urethra alongside the foreign body without any difficulty. A good view of the pencil was obtained, and the inscription on it could be clearly seen; there was a moderate cystitis. Suprapubic cystotomy was then performed. On opening the bladder the pencil was found to be lying vertically. Its unsharpened end was impacted in the mucosa of the fundus of the bladder, producing a small round ulcer but not penetrating the muscular coat. The distal end of the pencil lay in the prostatic urethra; the point penetrated the urethra in the region of the bulb and projected into the tissues of the perineum. The pencil was easily removed by disimpacting the proximal end and withdrawing the distal end from the urethra. It measured 6½ in. in length (Fig. 2). The bladder was closed with suprapubic drainage.

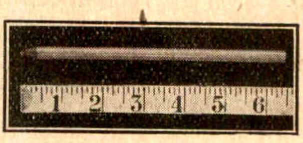

FIG. 2.—The foreign body.

The post-operative course was uneventful, the patient passing some urine naturally on the ninth day. At this time the suprapubic catheter began to leak, and was replaced by a Hamilton Irving box. The wound closed rapidly: at the end of 3 weeks it was dry and the patient up and about. He passed urine naturally, and at no time was there trouble in the perineum caused by the wound of the floor of the urethra.

COMMENT

On questioning the patient after operation he confessed that he had passed the pencil into his urethra many times, but that on this occasion it slipped out of reach and into the bladder without any great difficulty or pain. It is remarkable that an article of this length could so easily negotiate the natural curve of the urethra. True, the urethra had been dilated by previous attempts, and this was confirmed by the condition of the external urinary meatus and by the fact that the urethra could accommodate the foreign body and a cystoscope without difficulty. Presumably the point of the pencil was made to perforate the floor of the urethra by muscular contractions of the bladder during micturition.

My thanks are due to Dr. Gubbin, medical superintendent of the emergency hospital in which this patient was treated, for permission to publish this case; to Dr. Fraser for the radiograph; to Dr. Winternitz, my house-surgeon, for assistance in the treatment of this patient; and to Miss Lewis for the photograph.

Cheese Itch: Contact Dermatitis due to Mite-infested Cheese Dust

We would like to draw attention to a form of dermatitis affecting persons handling cheeses the surface of which has become infested with mites of the Tyroglyphus family.

Some months ago three such cases were seen among two separate gangs of workers who were unloading imported cheeses at the dockside. While manipulating the crates they became showered with a fine brown powdery dust which thickly coated the cheeses; some hours later an acute irritable erythematous dermatitis developed over their faces, necks, and flexor wrist areas. They stated that all the other men who came in close contact with the dust were also affected, though less severely. Samples of the dust were found microscopically to be teeming with mites which were subsequently identified by Mr. E. Browning, Department of Zoology, British Museum (Natural History), as *Tyroglyphus longior* var. *Castellanii*, Hirst, the mite which is responsible for eruptions in handlers of dried coconut kernel (copra itch). An account of these cases will be published shortly in the *British Journal of Dermatology*.

Just recently another group of cases has occurred at a provision depot among girls handling cheeses that had been stored for a considerable time. The dermatitis was of the same acute diffuse erythematous type and involved the same areas. A specimen of the cheese dust showed a heavy infestation of active Tyroglyphid mites with numerous ova and dead bodies.

It is noteworthy that, except for a few small urticarial lesions on the forearms in one patient, the eruption in no case suggested a parasitic cause, but was characteristic of dermatitis due to an irritant. Moreover, as all who were exposed to the dust seem to have been affected, it would appear that the mites must generate an irritant of considerable potency.

The dermatitis has subsided quickly, though in one case scaling of the eyelids persisted for over a fortnight.

Tyroglyphidae are of world-wide distribution and, apart from cheese, may attack foodstuffs of many kinds, such as flour, grain, sugar, dried meats and fruits, and jams. They may therefore present a problem not only as a cause of occupational dermatitis but as destroyers of stored foods, which is of added importance during wartime. In the case of cheese they live mainly in the rind and appear to cause little or no material damage to the cheese itself. They are not, of course, related in any way to cheese maggots, which bore into the cheese itself and are the larvae of a fly, *Piophila casei*.

Reviews

CYTOLOGY

Cytology and Cell Physiology. Edited by Geoffrey Bourne. (Pp. 296. 20s.) Oxford: The Clarendon Press.

It is to be hoped that the title of this book will not restrict its readers to cytologists. It contains a whole range of information on aspects of the subject on which attention is most focused now. This means that it provides both the outlook and the facts which are so essential to every biologist.

Knowledge of the morphology of the cell has not made any great advance recently, although much can probably be expected of new techniques such as micro-incineration and the electron microscope. But many facts of great interest have been found concerning the changes in structure in different physiological and pathological conditions. Knowledge of them would resolve many of the mysteries that worry those to whom cytology has until now appeared as an art of artefacts. Neurophysiologists have learnt to think of the mechanism of the nervous system in terms of the action of its component cells and the properties of their membranes. Others, such as biochemists, pharmacologists, and pathologists, will have to think more and more in terms, not of organs and tissue slices, but of cells and intracellular systems. It must not be thought that the debt will be one-sided. The cytologist owes much to a wide range of sciences. Physical chemistry has helped in the study of cell membranes; biochemistry has suggested methods for identifying enzymes within the cell; genetics has led to advance in the knowledge of the nucleus.

The standard of the work of the different contributors is uniformly high despite the difficult conditions under which they were working. Indeed it is just those chapters which appear to have been written in the absence of easy access to reference libraries that would be most readable and instructive for those whose interest in the subject is greater than their knowledge of it. The only criticism of the book that can be offered is that the system of references is very awkward to use. The publishers are to be congratulated on a production which is entirely of pre-war standard.

HISTORY OF MEDICAL PSYCHOLOGY

A History of Medical Psychology. By Gregory Zilboorg, M.D., in collaboration with George W. Henry, M.D. (Pp. 606; 19 illustrations. $5.00 or 28s.) New York: W. W. Norton and Company Inc.; London: George Allen and Unwin.

This handsomely produced book is a successful attempt to trace the development of beliefs, facts, and theories about the human mind in health and disease. Dr. Zilboorg contributes the first 12 chapters, and Dr. Henry the last two, on "Organic Mental Illnesses" and "Mental Hospitals." Among the illustrations is an unusual one of Freud.

For centuries psychology was the province of the philosopher and theologian, and was neglected by medical men; a history of medical psychology must therefore, Dr. Zilboorg remarks, be approached in a way "entirely different from that required by the history of medicine and surgery." For all that, he sticks fairly closely to the story of medicine, and it would not be unfair to describe his book as a history of medicine as seen through the eyes of a psychologist.

Hippocrates observed of epilepsy that it appeared to him "to be in no way more divine, nor more sacred than other diseases, but has a natural cause from which it originates like other affections"; and that "they who first referred this disease to the gods appear to me to have been just such persons as the conjurors, purificators, mountebanks, and charlatans now are." Hippocrates gave a rational classification of mental diseases, and looked upon the brain as the centre of reason, to be displaced later by Aristotle to the heart. To Hippocrates the action of the four humours on the brain was an important determinant of mental disorder. The clear-headed view of Hippocrates—that mental disease was the result of natural causes—was not followed by Plato, who said there were two kinds of mania, one due to disease, the other "a gift of the gods." So back again came the idea of the divine origin of mental disorder. Although Aristotle believed that the "souls" of man acted as a unit, he considered that reason was independent of man or matter, and that it could not be attacked by illness because it was immaterial and immortal. This view, Dr. Zilboorg states, played a decisive part in the history of psychiatry, because it "naturally must reject the very existence of purely psychological troubles."

In the second and first centuries B.C. gleams of clear light in the history of medical psychology illumine vividly the darkness into which men were to descend centuries later. Asclepiades, it appears, realized that mental disease could be due to emotional disturbances: he prescribed baths, "musical harmony and a concert of voices" for his patients; and condemned the practice of keeping the mentally sick in cells and dungeons.

Dr. Zilboorg gives some remarkably interesting quotations from Cicero, worth reproducing here: "Man being composed of body and soul," Cicero writes, "why is it that so much attention has been paid to the art of the preservation of the body and the curing of bodily ills; why is it that this art, which because of its usefulness was attributed to the power of the gods, has so badly neglected the development of the art of healing the soul?" "Is it," Cicero asks, "that the ailments of the soul are less injurious than physical ailments, or is it that physical ailments admit of treatment while there is no means of curing souls? But diseases of the soul are both more dangerous and more numerous than those of the body."

Living in the first century of our era, and practising in Alexandria and Rome, Soranus of Ephesus was notable for his insight into mental conditions and his humane approach to treatment. He condemns the use of force and the excessive employment of drugs and purgatives. "Much tact and discretion," he said of mental patients, "should be employed in directing attention to their faults; sometimes misbehaviour should be overlooked or met with indulgence." "Maniacs must be placed in a moderately lighted room, which is of moderate temperature and where the tranquillity is not disturbed by any noise. . . . Their beds should be solidly fastened and placed in such a manner that they do not see persons who enter; a variety of irritations is thus avoided." (Soranus, it may be recalled, advocated blocking the mouth of the uterus with cotton or ointments to prevent conception.) And so we come to Galen (A.D. 129–200), of whom Prof. Major Greenwood says, ". . . It is *only* the psychological aspects of his teaching which have survived the collapse of Galenism as a medical system."

The above is a brief summary of the first four chapters of Dr. Zilboorg's book. Then follow chapters called, "The Great Decline"; "The Ruthless Surrender to Demonology"; "The Blows of the Witches' Hammer"; "The First Psychiatric Revolution"; "The Age of Reconstruction"; "The Discovery of Neuroses"; "The Era of Systems"; "The Second Psychiatric Revolution"; "Epilogue." Dr. Zilboorg naturally gives a lot of space to Freud, but his treatment of Adler and of Jung, especially the latter, is too summary. It is odd that both Roger and Francis Bacon are not separated in the index, sharing the one entry, "Bacon." Dr. Zilboorg's style is undistinguished, and might well have been more terse. For his industry in compiling a book packed with so much interest, medical men devoted to the history of their profession will be much indebted.

DIRECTORY FOR THE DISABLED

Disabled? Inquire Within. Central Council for the Care of Cripples, 34, Eccleston Square, London, S.W.1.

This useful booklet has been produced with the object of assisting citizens' advice bureaux, hospital almoners, and social workers whose duty it is to direct disabled persons to sources of appropriate help. Whether disablement is the result of crippling disease, or of injury sustained in war service, in air raids, or in industrial accidents, there is now a large network of provision covering the country—though some areas are better provided than others—which it is very useful to have catalogued.

The booklet first describes the statutory services which are available, principally through the Ministries of Health, Labour, and Pensions, and then gives a list of the voluntary agencies and their particular functions. The Central Council for the Care of Cripples itself is a co-ordinating agency for all organizations working for the welfare of cripples. There are also the After-Care Association, the Invalid Children's Association, the Royal Surgical Aid Society, the British Legion, and various organizations for Service people. Then a brief description is given of the means of treatment, education, and after-care available to the physically defective child and the services for the physically disabled adult, including the orthopaedic sections of Service hospitals and the arrangements for dealing with air-raid casualties, industrial workers, and civilian disabled in general.

The impression obtained from this booklet is of an abundant provision, though it needs to be set over against the vast—indeed the appalling—extent of crippledom of one sort or another. The Ministry of Health has lately established under the Emergency Hospital Scheme seven orthopaedic centres in the London sectors and eleven in other regions of England and Wales. But there is only one in Yorkshire and only one in Northumberland and Durham. Fracture departments have been set up by the Ministry—56 of them for long-stay cases and over 200 for ambulatory and short-stay—but in Yorkshire and Northumberland and Durham there are only five of the former compared with twenty in the London sectors. Particulars are also given of the various Government and other schemes for the training and resettlement of disabled persons, including the arrangements for occupational therapy set up in E.M.S. and other hospitals and for vocational training under the Ministry of Labour's scheme. This booklet will be of service to many medical practitioners, especially in industrial areas.

Notes on Books

A Bibliography of Aviation Medicine, by **Ebbe Curtis Hoff** and **John Farquhar Fulton**, is published in London by Baillière, Tindall and Cox at 22s. This is an amazingly complete and up-to-date collection of over 5,000 references. It contains little explanatory subject-matter, for the clear indexing and tabulation are self-sufficient. The articles are listed under subject headings with detailed subheadings, and there are also alphabetical indices of authors and subjects. Several smaller bibliographies of aviation medicine have appeared before, but the present large volume prepared for the Committee of Aviation Medicine of the National Research Council of America will supersede all others and will be invaluable to that rapidly growing army of research workers who are helping the flying man to meet the increasing demands made by his machine.

The thirteenth edition of *Pye's Surgical Handicraft* is the third since Mr. **Hamilton Bailey** took this work in hand. Destroyed by enemy bombing while in preparation, with the loss of the illustration blocks and a large number of the original illustrations, this edition was again bombed when just about to be published. Its birth therefore has been a difficult one, for the ultimate success of which both authors and publishers are to be congratulated. Several of the forty contributors are now serving as members of H.M. Forces. The useful and practical features of this book are too well known to require further comment. The tribute paid to Walter Pye, the original editor who died in 1892, could be enhanced by a few words as to who he was, what his appointments were, and the nature of his work, while it would add to readers' interest to know who the intervening editors have been. What from the vicissitudes attending its production appeared to be an unlucky thirteenth edition may well prove to be the most popular and most successful printing which this well-known book has yet had. It is published by John Wright and Sons, Ltd., at 25s.

Beaumont's classical observations and experiments on Alexis St. Martin really provided the basis for the modern study of gastric digestion. Indeed he noted points which remained neglected for many years and in which interest was only revived in the 20th century, such as the regurgitation of bile and the psychical factor in gastric secretion. Dr. **George Rosen** gives an interesting account of *The Reception of William Beaumont's Discovery in Europe* (Schuman's, 20, East 70th Street, New York; $5.00). In this he shows that Germany first realized its significance, and England soon after. Its recognition in the United States, its home of origin, came decidedly later. The introduction of the stomach tube by Kussmaul in 1867 completely diverted interest from Beaumont's work until the time of Pavlov. The book is well documented and well produced, but we hesitate to recommend the expenditure of a sovereign for its 86 pages at the present time.

The report prepared by "Mass Observation" for the Advertising Service Guild entitled *People in Production* was noticed on its first appearance in a leading article in our issue of May 16, 1942, under the heading "Morale on the Home Front." This interesting document on British war production has now been reissued as a Penguin Special of 280 pages at the low price of 9d.

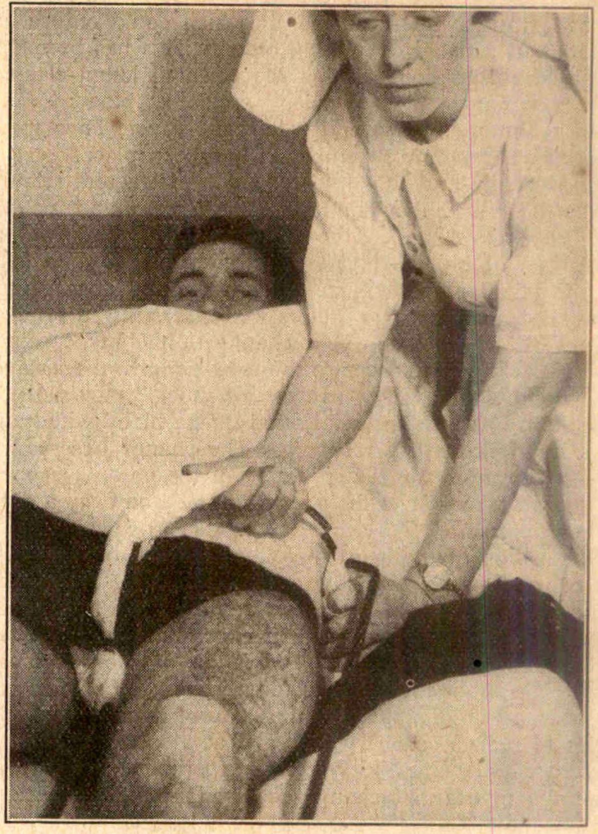
Preparations and Appliances

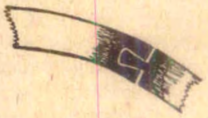
A MODIFICATION OF THE THOMAS SPLINT

Dr. M. P. **Laufer** writes from the County Hospital, Keighley:

To apply a Thomas splint to a seriously injured limb is often a very difficult matter. The main difficulty consists in the sliding of the ring up the whole length of the injured limb without pain, discomfort, or displacement.

The modified Thomas splint, as here portrayed, dispenses with all the difficulties attached to the application of the ordinary splint. Its advantages are easily enumerated: (1) There is no need to slide the ring up the limb; it is put around it. (2) The handling of the injured limb is reduced to a minimum. (3) The danger of increasing shock and displacement is lessened. (4) The number of helpers is substantially reduced. (5) The hinge is 1½ in. away from the joint formed by the internal bar and the ring; it is just outside the part of the ring which represents the effective area essential for the immobilization of the limb. (6) The "lock" is simple and secure; it is opened and locked by pulling the movable part of the ring in axial direction; the "spring" action of the halved ring makes it possible. (7) The lock is outside the pressure area. (8) Last but not least, the modification is easily made on any Thomas splint with a minimum of cost.





The photograph shows the locking of the ring. At this stage the areas of hinge and lock may be padded. The line drawing gives details of the "lock."

First-aid teams who have not the benefit of an anaesthetist's help to effect painless application of the ordinary Thomas splint to a severely injured limb will be the first to profit by the modification.

SOME ASPECTS OF SHOCK THERAPY

The gradual deterioration of the clinical condition which occurs in some cases of tissue trauma or severe haemorrhage in spite of repeated transfusions of blood or blood substitutes is only too painfully familiar. It is believed that this failure of transfusion therapy is due in large measure to a breakdown in the mechanisms involved in maintaining an adequate volume of blood. Various explanations have been given of the causes of failure, but none of them has been satisfactory. They have been concerned mostly with those factors which could reduce the amount of actively circulating blood. This has been due to the widespread belief that the essential lethal element is a reduction in the volume of circulating blood.

In recent months several significant papers have made it clear that too much emphasis has been placed on the blood volume and too little on the other factors relating to the heart and the blood vessels. Wiggers and his colleagues[1] [2] have studied the effects of the withdrawal of quantities of blood equal to approximately 40% to 50% of the initial blood volume in anaesthetized dogs. They showed clearly that two factors were necessary to produce "irreversible shock": (1) a change in the myocardium, and (2) a failure to increase the total peripheral resistance in the circulation. By "irreversible shock" they meant a condition in which the reinjection of the blood withdrawn was not followed by recovery. The change observed in the myocardium was a diminution of the normal response of the heart muscle to the stretch imposed on it by a given venous pressure. This change was due to impairment of the nutrition of the heart muscle as a result of a reduced coronary flow from a low arterial pressure. The other finding that the total peripheral resistance of the circulation was never maximal in their experiments suggests that there was some degree of depression of the vasomotor centres in the medulla. The failure to increase peripheral resistance would rapidly yield a state of hypotension sufficient to reduce coronary flow and accelerate the onset of myocardial damage. In Wiggers's experiments it was found that the myocardial change occurred in the presence of an adequate blood volume and was independent of haemoconcentration and haemodilution. If it be considered that the precipitating factor was the persistent hypotension, this might have been due to the action of the anaesthetic on those centres which would normally act to restore arterial pressure. This view receives support from the work of Fine *et al.*,[3] who noted that, while haemorrhages up to 40% of the blood volume did not cause a persistent hypotension in unanaesthetized animals, the same amount of haemorrhage caused permanent hypotension in animals anaesthetized with nembutal. It is significant that both groups of workers used barbiturate anaesthetics, which are known to depress the hypothalamic and medullary cardiac and vasomotor centres.

Dr. Lena Stern, in an article in our present issue (p. 538), has introduced a new treatment of shock which depends on a method of stimulating these cardiovascular centres directly. Without knowledge of the work of Wiggers and of Fine she has focused her attention on the condition of the vegetative nervous system and concluded that there is a reduction in the activity of the sympathetic system simultaneously with an increased stimulation of the parasympathetic. On the basis of her work on the potassium–calcium balance in the cerebrospinal fluid (c.s.f.) she decided to attempt to raise the potassium content of the intraventricular c.s.f. and in this way to increase the activity of the sympathetic while inhibiting the parasympathetic by a direct effect of potassium ions on the ganglion cells. Without increasing the blood volume by transfusion. Dr. Lena Stern observed that intraventricular injections of a potassium salt immediately raised the blood pressure and apparently brought the animal out of shock. These findings have been applied successfully to the treatment of war casualties.

Unfortunately, no details of the types of case treated are given, and so one cannot evaluate the new method of treatment. That it should fit in with the papers referred to above is a happy and timely coincidence. One point may be discussed further. Dr. Stern considers a state of parasympathetic hyperactivity to exist with depression of the sympathetic centres. The observation of Wiggers *et al.*[1] that the myocardial defect was a lack of response to stretch suggests that this defect may be attributable in part to vagal overactivity—first, by diminishing the calibre of the coronary vessels, and, secondly, by releasing potassium ions, which act directly on heart muscle. Winkler *et al.*[4] in 1938 showed that only a small increase in blood potassium was necessary to cause obvious electrocardiographic changes, and these were due to effects on the myocardium. When the potassium concentration was gradually raised there was cardiac failure in diastole, with the dilated heart observed in cases of experimental shock from trauma or haemorrhage. In the cardiac failure that finally takes place potassium may well be the lethal agent. Scudder,[5] in 1940, stressed the part played by potassium poisoning in shock and suggested the use of adrenal cortical hormone as a remedy. Unfortunately, expectations have not been realized. The reasons for the partial failure have been studied by Fine *et al.* They showed clearly that cortin alone is ineffective in treatment of shock, but when saline solutions are given intravenously with cortin there is in some animals a rise in arterial tension which tends to be maintained. Desoxycorticosterone acetate is ineffective either alone or with saline infusions. It would seem, therefore, that with the present evidence treatment should be aimed at increasing peripheral resistance and not at eliminating excess potassium from the myocardium. Given an efficient coronary flow by relaxation of coronary vessels and increased arterial tension, any potassium excess in the myocardium would be speedily dissipated.

Although there are many gaps yet in the evidence, it is clear that Dr. Stern has come forward at the right moment and has reoriented our views on the treatment of shock. That does not mean, however, that transfusions will cease to be used. Her work will need confirmation; and, granted that confirmation is forthcoming, it would appear that Dr. Stern's treatment should be reserved for those patients who do not show progressive increases in arterial tension as transfusions are given. Whitby and his colleagues[6] have made it clear that the gradual stepping up of the arterial tension with successive transfusions is the best prognostic feature in treatment of haemorrhage and shock from injury.

FOETAL AND POST-NATAL CIRCULATION

The solution of the various problems which are encountered in the study of the foetal and post-natal circulation of the blood has attracted the attention of scientific workers since the times of Galen, who first described the foramen ovale, and who has himself been described as the "founder of modern physiology." He was succeeded in the seventeenth century by Harvey, Lower, and others. More recently the early embryonic stages in the development of the heart and vascular system have been studied by means of serial sections and reconstruction models by His, Born, Tandler, Prentiss, and many others. The work accomplished by these pioneer investigators, and the inferences made by them, have now in large measure been confirmed and have received a new impetus from records demonstrating the actual course of the circulating blood currents obtained by modern methods of technique, which at the suggestion of Sir Joseph Barcroft and Dr. H. Barron have been utilized and adapted for the study of the foetal circulation by Dr. A. E. Barclay, Dr. K. J. Franklin, and Mr. M. M. L. Prichard.[1] These workers have employed direct and indirect *x*-ray cinematography, combined with intravascular injection of radio-opaque media, in the investigation of the time and manner of closure of the ductus arteriosus, the closure of the foramen ovale, and the intracardiac flow of blood reaching the heart through the superior and inferior venae cavae, and also the circulation of blood reaching the foetus by the umbilical vein through the liver and ductus venosus. This work, which has been carried out at the Nuffield Institute for Medical Research, Oxford, has been extended, and was also preceded by other experimental work on the foetal circulation, including that in the pulmonary vessels; this has been supplemented by a valuable historical record of the literature and studies in comparative anatomy and embryology contributed by Dr. E. C. Amoroso of the Royal Veterinary College, London, Dr. K. J. Franklin, and others.

It will not be possible in this short article to do more than give a brief summary of some of the more important results that these authors have been able to demonstrate in living eutherian foetuses (principally sheep) delivered by Caesarean section and photographed while the foetus was still in connexion with the uterus by means of the placenta and vessels of the umbilical cord. In these operations a radio-opaque material was injected into one of the foetal veins (external jugular, femoral, or umbilical) and respiration prevented, so as to disturb the conditions of intra-uterine life as little as possible. Perhaps the most striking results which have been demonstrated by these means are: (1) The division of the inferior or posterior vena-caval flow into two streams, (*a*) a larger passing through the foramen ovale into the left atrium, and (*b*) a smaller which enters the right ventricle through the right atrio-ventricular or tricuspid orifice. (2) The flow of the whole of the superior or anterior vena-caval blood through the right atrium and right ventricle into the pulmonary trunk, and by the ductus arteriosus into the descending aorta and pulmonary arteries. (3) The flow from the placenta via the umbilical vein to the inferior vena cava; a small portion only of this blood is by-passed through the ductus venosus, and enters the inferior vena cava directly; the larger portion traverses the liver substance through branches of the umbilical vein, which carry the blood to the hepatic sinuses and so to the large hepatic veins which open into the posterior vena cava. (4) Lateral radiographs of the circulation through the heart of a foetal lamb have also been obtained which show the influence of the tubercle of Lower—well developed in the sheep—in directing the anterior vena-caval inflow, and thus preventing a mixture of this current with that which passes from the posterior vena cava through the foramen ovale.

The division of the posterior vena-caval inflow into two divisions was inferred in 1776 by C. F. Wolff, who estimated that "towards full term about two-thirds of the inferior vena-caval blood would take the left-hand route and about one-third the right-hand one." Wolff's work did not become generally known, but was confirmed by Ziegenspeck in 1905 in guinea-pig and human hearts. Ziegenspeck made drawings of the relation which the caudal, lower edge of the interatrial septum has to the posterior vena-caval channel, as seen when looking at it from below, through a transversely divided posterior vena cava in an excised foetal heart. The actual division of the inflowing blood from the posterior vena cava in the circulating blood stream of the living foetus has, however, been demonstrated for the first time by the writers whose work we are considering, as well as other records of the circulation in the intact foetus.

From the physiological point of view, and owing to variations which are met with in different types of animals rendering inappropriate certain terms that are now used in human anatomy, the authors have found it necessary to introduce some new names. Thus the projecting ridge which divides the posterior vena-caval channel into right and left terminal divisions is named the *crista dividens*, and the boundaries of the foramen ovale are described as (*a*) *a fixed portion*, consisting of the curved lower edge of the upper part of the annulus ovalis (septum II), and (*b*) an *apposable portion*, the valve of the foramen ovale or upper free portion of the septum primum, which overlaps the fixed portion, or "crista dividens," on its left side.

IMMUNIZATION AGAINST INFLUENZA

Early and inconclusive attempts to immunize against influenza with virus vaccines have been followed up in the United States, and several prolonged and painstaking studies have now been reported. The problem is far more complex than it originally appeared, for it is now known that at least two distinct viruses are concerned, and other indistinguishable cases occur in which the causal agent is unknown. The virus originally isolated by Andrewes, Laidlaw, and Wilson Smith is designated virus A; the unrelated virus B was identified by Francis two years ago; and influenza from which neither of these can be recovered is known as influenza Y. That the first two are immunologically quite distinct is confirmed by the observations of E. R. Rickard, F. L. Horsfall, G. K. Hirst, and E. H. Lennette[1] on the relation between the antibody content of the blood and susceptibility to influenza. Whereas a high antibody level is correlated with immunity to the corresponding virus, susceptibility to the other is unaffected. They make a further deduction which is quite unexpected and somewhat disturbing—that the higher the degree of immunity to either of the known viruses, the greater is susceptibility to influenza Y. This conclusion seems to suggest that a factor apart from humoral immunity must take part in determining susceptibility to influenza. The same workers[2] describe a clinical experiment on a large scale in which some of the inmates in a number of State institutions were inoculated with a formalinized vaccine of virus A and canine distemper virus.

[2] Ibid., p. 1863.

The effect on serum antibody to virus A was determined by neutralization and complement-fixation tests, and the aetiology of subsequent cases of influenza was verified in the same way. Their conclusion is that the incidence of influenza A was significantly reduced. On the other hand, M. Siegel, R. S. Muckenfuss, M. Schaeffer, H. L. Wilcox, and Ann G. Lieder,[3] in a study carried on over four years in a large institution for mental defectives, and employing similar vaccines, reach the discouraging conclusion that immunization had no effect in reducing the frequency of influenza, whether due to virus A or to other organisms. This is not only a prolonged but a detailed and thorough study, and its circumstances—confinement to a single large institution with patients under complete control, and the alphabetical separation of inoculated and control cases—entitle it to serious consideration. Several incidental observations made are not encouraging, and perhaps the least hopeful feature of the whole subject is the evidently transient nature of immunity, however produced. Not only does the antibody titre decline demonstrably within a few months of vaccination, but in several cases repeated attacks of influenza due to virus A were observed, indicating that the infection itself does not necessarily confer a lasting immunity. If this is generally true of the natural disease, what can be expected of any method of artificial immunization? In all these studies the vaccine contained inactivated virus; living virus was employed in earlier American studies, and it is of interest in this connexion that F. M. Burnet,[4] who has succeeded by intratracheal injection in producing influenza A in *Macacus cynomolgus* (*M. irus*), found vaccination in this animal by the subcutaneous route to be effective only when living virus was used. Taking this evidence as a whole, it cannot be said the influenza virus vaccines now available have much claim to be regarded as satisfactory immunizing agents. All this takes no account of the common cold, in which other viruses are believed to be concerned. An altogether new approach to this problem seems necessary if any real progress is to be made.

EPILEPTOGENIC PROPERTY OF SULPHATHIAZOLE

The local application of the sulphonamide drugs to wounds has recently been employed to a considerable extent. In this use sulphathiazole has been found in many respects unsatisfactory, and it is now apparent that, applied to the cerebral surface, it is apt to be particularly dangerous. Watt and Alexander[5] report 10 cases in which craniotomy was performed and sulphathiazole applied to the wound intradurally or extradurally after suture of the dura, as a prophylactic against operative infection. In 6 cases the craniotomy was frontal; in 5 of these the dura was opened (in one case merely punctured for ventricular tapping), and all 5 developed early post-operative epileptic attacks, often with focal features. The attacks generally ceased within a few hours, but 2 of the patients passed into status epilepticus and died. In the remaining frontal case the thickened dura was not opened, and it presumably provided an effective barrier against diffusion of the drug in solution towards the underlying brain. The remaining 4 cases of the series were spared the epileptic complication, and in these the craniotomy was lateral or posterior in position; the dura was widely opened. It is interesting that in one case of this group there was focal epilepsy as a leading pre-operative symptom, yet there was no post-operative complication; in contrast, all the affected cases had no previous history of epilepsy. The authors, in animal tests, found that in 9 out of 10 experiments sulphathiazole applied to the cerebral surface is a powerful epileptogen. This property was found not to be related to sterilization of the powder or to the source of manufacture. Their experiments also confirmed the clinical experience that sulphapyridine is not an epileptogenic substance, and sulphadiazine and sulphacetamide were found to be innocuous. Simultaneously and independently Pilcher, Angelucci, and Meacham were working on a similar experimental investigation in a larger series of animals. In a preliminary report[6] they also sound a warning against the use of sulphathiazole intracranially. In a high percentage of their experiments the application of sulphathiazole to the surface of the brain was followed by epilepsy with focal characteristics. The concentration of the drug in the blood and the cerebrospinal fluid remained at a low figure.

These observations, when followed up, may perhaps throw some light on the causation of epilepsy. But the important practical point that emerges is that sulphathiazole may not be used with impunity in proximity to the brain. It is also apparent that other chemotherapeutic substances, as they become available in the future, must be fully tested experimentally before they can be employed clinically.

EGG-WHITE INJURY IN MAN

Last year (Oct. 11, 1941) it was noted in this *Journal*[7] that it had not yet been shown that biotin, vitamin H, or co-enzyme R (probably all the same substance) was necessary for man. This year Sydenstricker and his colleagues[8] have reported certain symptoms in four patients (three white men and one negro woman) who volunteered to eat a diet free from biotin and rich in egg-white. The diet consisted of a mixture of 125 g. rice, 80 g. white flour, 75 g. farina, 205 g. cane sugar, 32 g. lard, 10 g. washed butter, 25 g. lean beef, and 200 g. dehydrated egg-white. This represented 387 g. carbohydrate, 31 g. protein other than egg-white, and 32 g. fat, with a total caloric value of 1,960 daily. In addition 928 calories were derived from the 160 g. protein and 32 g. fat in the egg-white, making a total daily caloric intake of 2,888. This diet was poor in all vitamins except riboflavin, which was present to the amount of 10 mg. per 100 g. of egg-white. The following supplements were therefore given daily: thiamine hydrochloride 6 mg., riboflavin 9 mg., nicotinic acid 75 mg., pyridoxine 5 mg., calcium pantothenate 5 mg., ascorbic acid 75 mg., vitamin A 5,000 units, ferrous sulphate 1 g., and calcium lactate 1 g.

At the beginning of the experiment all the subjects were in good general condition and free from symptoms and signs of avitaminosis. During the third and fourth weeks all developed a fine scaly dermatitis which did not itch and which disappeared spontaneously. In the seventh week one patient came out with a maculosquamous dermatitis of the hands, arms, and legs. During the seventh and eighth weeks all showed a greyish pallor of the skin, which, being out of proportion to the blood picture, was interpreted as evidence of peripheral vasoconstriction. The three white patients showed definite atrophy of the lingual papillae, patchy with the production of a "geographic" tongue in one, general in another, and on the lateral thirds of the tongue in the third. The negro woman's tongue was not affected until the fourteenth week. None of them showed the capillary engorgement seen in pellagra or ariboflavinosis. Dryness of the skin of the extremities with well-defined reticulation and a tendency to fine branny desquamation developed again in the ninth and tenth weeks. No ocular or genital lesions were observed. After the fifth week many of the symptoms associated with vitamin B_1 deficiency began to appear —e.g., mild depression to extreme lassitude, muscle pains, hyperaesthesia, and anorexia. There was a diminution in the haemoglobin content of the blood, the number of erythrocytes, and the volume of packed red cells, in spite of a theoretically adequate intake of iron and protein. The daily excretion of biotin fell from the 29–62 µg. of persons taking a normal diet to 3.5–7.3 µg. When a biotin concentrate was injected (75–300 µg. daily), depression, muscle pain, precordial distress, and anorexia were abolished on the third to fifth day of treatment. The ashy pallor disappeared in four days. The urinary excretion of biotin rose to 55 µg. and later, with a larger intake, to 150 µg. per day. When medication ceased it fell to a level slightly below that of patients eating a normal diet. Thus the experiment seems to afford clear evidence that biotin is essential to the nutrition of man.

GASTRIC SECRETION AND ULCER

Peptic ulcer arises only in those parts of the digestive tract exposed to the action of acid gastric juice, and all experimental and clinical research seems to prove that both acid and pepsin must be present if ulceration is to occur. Exactly how the normal gastric mucosa is protected from acid digestion, and how tissue resistance, gastric secretion, and acid neutralization are precisely interrelated, are not yet fully known. Certainly the healing of chronic ulcer is not prevented by the presence of gastric acid, and such things as tone, motility, emptying time, and spasm have all to be taken into account.

Some of the many aspects of this subject were recently reviewed by Ivy[1] in a lecture under the title, "The Mechanisms of Gastric Secretion," in which he emphasizes again the two periods of gastric secretion—first, the continuous (or interdigestive), and, secondly, the digestive. The former is perhaps too often overlooked; it occurs when the stomach is empty, persists throughout long fasts, and is of variable amount and acidity. The nature of the stimuli which give rise to this continuous secretion is uncertain. It goes on during sleep, and Dragstedt[2] noted that in patients with duodenal ulcer the fasting night secretion of gastric juice totalled from 500 to 1,200 c.cm., compared with usually less than 300 c.cm. in normal persons. Experimentally it is possible in animals, by keeping up stimulation, to increase this continuous secretion, and in such cases typical chronic perforating ulcer has been produced (S. H. Walpole and others[3]). Ivy also points out that the continuous secretion is increased by operations on the upper abdomen, and describes how, after a Pavlov pouch has been made in the dog, the pouch will "hypersecrete" for days or weeks on end. Such secretion is diminished by atropine, though not abolished. The second period of digestive secretion is made up of three phases —the cephalic, the gastric, and the intestinal. The first of these acts through the appetite and is dependent upon both conditioned (cerebral) and unconditioned (noncerebral) reflexes, the vagi containing the excitatory nerves, which are inhibited by atropine and may be interrupted by cutting. Vagotomy as a treatment for ulcer will therefore depend for its effects largely upon how far the cephalic (or nervous) phase of gastric secretion is contributing to the total secretion in the individual concerned, as well as upon the other results of vagal section on gastric tone, emptying time, and circulation. The gastric phase is governed by mechanical distension of the stomach, and partly by chemical secretagogues either present in food (e.g., lean meat) or arising from its digestion. The intestinal phase is entirely concerned with chemical substances which stimulate gastric secretion when applied to the intestine, of which soap, fatty acids, and peptone are examples. Neutral fat, on the other hand, when present in the small intestine inhibits gastric secretion through the production of a substance—enterogastrone—acting through the circulation. Gastric evacuation is largely determined by the antral tone, antral contractions, the activity of the pyloric sphincter, and the character of the food. The intestine also exerts control over the pylorus.

These various phases of gastric secretion may be considered from the standpoint of treatment: for example, the possibility of controlling the continuous night secretion by atropine, the inability of gastro-enterostomy to influence the cephalic or intestinal phase of secretion, the significance of mechanical distension in provoking gastric stimulation. Various extracts resembling enterogastrone in their action have been applied as inhibitors of secretion; but so far the only extract to be used with success has been that of the posterior pituitary.

Whatever may be the ultimate cause of peptic ulcer, the immediate lines of attack on questions of aetiology and treatment would seem to be by way of a thorough understanding of the mechanisms of gastric secretion and movement.

GOOD AND BAD CHEMOTHERAPY FOR GONORRHOEA

Among experts in the treatment of gonorrhoea it has become a truism that the quicker a patient is cured the less chance (*a*) of his spreading the disease, (*b*) of his default before cure, (*c*) of his developing a blood dyscrasia, and (*d*) of the infecting gonococci becoming drug-resistant. Last week we published at p. 528 a letter from Col. L. W. Harrison, Adviser on Venereal Diseases to the Ministry of Health, appealing to all practitioners to help in the campaign against this disease by using sulphonamides for the treatment of gonorrhoea in such ways as are calculated to make the patient non-infectious as quickly as possible and to run the least possible risk of creating sulphonamide-resistant strains of gonococci. Col. Harrison's letter gained reinforcement from a letter published simultaneously from Dr. P. W. Hamond, medical officer in charge of the Croydon V.D. Clinic, who also deprecated the custom of giving sulphapyridine at sight in cases of urethritis without any bacteriological confirmation of the diagnosis and in doses likely to encourage a drug-resistant strain of organisms. It appears from these letters that many doctors are ruining the chances of eradicating gonorrhoea, and are often promoting its spread, by a timid haphazard dosage. There is now good evidence, says Col. Harrison, that administration of 5 grammes of sulphathiazole on two successive days eradicates gonorrhoea, in males at least, in over 90% of cases, and four days' treatment on the same lines gives still better results; "in neither case does such a dosage give rise to any undue proportion of toxic effects, provided that the patient is made to drink plenty of water during the period of the chemotherapy."

Mr. L. R. Braithwaite will deliver the Bradshaw Lecture, on "The Role of Bile in Duodenal Regurgitation," at the Royal College of Surgeons of England, Lincoln's Inn Fields, W.C., on Thursday next, November 12, at 3.15 p.m.

War Medicine Series

The paper printed below is based on a lecture which was one of a series recently given at the British Postgraduate Medical School, Hammersmith

TETANUS

BY

LESLIE COLE, M.D., F.R.C.P.

The causal organism of tetanus, *Clostridium tetani,* is a rod-shaped Gram-positive organism. Its most important attributes are that it produces spores which are highly resistant, that these spores germinate in wounds only under anaerobic conditions, and that it produces an exotoxin which is absorbed and has a strychnine-like action on the cells of the central nervous system. It is prevalent in soil and is a common inhabitant of the digestive tract of many domestic animals, particularly horses. Perhaps for this reason the disease is most often found in agricultural districts, where the spores are spread by manure and horse ploughing.

Predisposing Causes

The incidence of tetanus in a district or on a battlefield depends partly on the prevalence of spores in the soil and partly on the type of wound. Deep, penetrating, or lacerated wounds allow spores to develop under anaerobic conditions, and growth is also favoured by pyogenic or other anaerobic infection and the presence of tissue necrosis or foreign bodies. Such conditions are a commonplace of modern war. On the other hand, uncleanliness of slight or superficial wounds with scab formation, sealing of slight wounds, or infection of body cavities may also lead to tetanus, and these are now the chief sources of infection in civilian practice. Whitlows in agricultural workers are a not uncommon cause of severe tetanus. Other, though unusual, sources of infection are intramuscular injections, grey wool used in padding plaster-of-Paris splints and infecting the wound under the plaster, felt applied over a pressure sore, infected catgut, puerperal sepsis, and umbilical infection in the newly born.

With the widespread use of prophylactic antitoxin the type of wound which causes tetanus has been profoundly modified. After the obvious wound it is prevented, but it tends to crop up when least expected.

Prevention

With thorough organization it should be possible to prevent tetanus entirely, but once the disease has developed only a certain proportion of patients can be saved. Prevention is therefore of supreme importance, and two methods are now available.

Passive Immunization.—This is attained by injecting a small dose (3,000 I.U.) of antitoxin soon after a wound has been received. The value of this was proved when it was first introduced on a large scale during the early months of the war of 1914-18. The figures given by Bruce show that when this was done the incidence of tetanus fell from 9 per 1,000 wounded in September, 1914, to 1.4 per 1,000 in the November. Even when this does not prevent the disease entirely it usually lessens the severity and lowers the mortality. After prophylactic antitoxin cases generally have a long incubation period, relatively frequent local tetanus, and a slow onset of reflex spasms or sometimes none at all. It is important to remember that the passive immunity conferred by one such injection lasts only between two and three weeks, so that a wound in which infection with tetanus persists will produce the disease at the end of this time if no further prophylaxis is given. For this reason the injection should be repeated at weekly intervals after severe wounds, and an injection should always be given before operation or manipulation of old wounds because these have been known to stir up a latent infection. After some very severe heavily infected wounds the first prophylactic dose may with advantage be doubled.

Active Immunization.—Ramon and Zoeller showed that this could be produced by injections of formolized toxin (toxoid), and a modification of their method is now used in the British Army. Two injections of 1 c.cm., at an interval of six weeks, are given to the soldier before he goes on active service, and this procedure seems to confer immunity for a year and probably much longer. It is very important to remember that the rise in antitoxin titre is much greater after the second injection than after the first, so that a single injection has comparatively little immunizing power and the second must be given. It has been shown that the immunizing effect of toxoid is increased if it is given with T.A.B., and the two may therefore with advantage be combined.

The Passive and Active Methods Compared.—The disadvantages of the passive method are that antitoxin has to be given soon after a man is wounded, which is not always possible in modern war; that, occasionally, severe reactions follow or sensitivity to horse serum, given later, is produced; and that even when repeated the antitoxin does not always completely protect. The active method, on the other hand, only rarely produces slight reactions, has the great advantage that it can be completed before the soldier goes on active service, and does not need to be repeated until a year or more. Its efficacy has not yet been tested out on a mass scale over a long period, but experimental evidence and practical experience in this war suggest that it is reliable. For reliance to be placed on this method alone in an army it is clear that every man must be immunized; therefore it is important that exact records of injections should be included in his papers. At present both methods are used; prophylactic antitoxin being given to all wounded even if they have already been actively immunized.

Description of the Disease

At onset typical tetanus is characterized by fleeting pains, chiefly in the neck and back; these are followed by the gradual onset of stiffness, first affecting the masseters so that there is difficulty in opening the mouth, and later the muscles of the trunk so that the spine is rigid and slightly arched and the abdomen board-like. In the early stages the eyebrows are drawn up, with wrinkling of the forehead, and the corners of the mouth are drawn back, producing a peculiar facial expression called the risus sardonicus. Dysphagia is sometimes an earlier symptom than trismus. The severer the case the more rapidly rigidity and trismus increase, and they tend to be more and more increased by manipulation or movement. This reflex excitability gradually becomes greater until sudden reflex spasms occur in which the jaws are forcibly clenched, the chest is fixed so that respiration is temporarily stopped, and the spine arched backwards in the position called opisthotonos. These reflex spasms may come on any time from twelve hours to seven days after the first onset of trismus, and the earlier they begin the more severe and fatal is the disease likely to be. The time between the first appearance of trismus and the establishment of reflex spasms (period of onset) can generally be estimated to within six hours, and is a good indication of prognosis. If it is less than forty-eight hours, death usually takes place within six days whatever is done; but if it is longer than this there is a good chance of recovery, which becomes greater as the period lengthens. In severe cases which recover, reflex spasms may continue to occur over a period of three weeks, increasing to a maximum, waxing and waning for a time, and then gradually getting less severe until they cease, leaving only tonic rigidity, which may persist for several weeks more, but eventually passing off. Reflex spasms are dangerous because they stop respiration, sometimes for several minutes, make feeding impossible, and exhaust the patient. Tonic rigidity in itself is harmless. In fatal uncomplicated cases death usually takes place within six days either from prolonged respiratory spasms, if these are not controlled, or from cardiac failure when toxin reaches vital centres in the medulla. It is often preceded by hyperpyrexia.

Clinical Types

For convenience tetanus may be divided into five types, as follows:

Type 1, in which at onset there is local tetanus in the wounded limb with rigidity or twitching, and in which the typical generalized picture appears later.

Type 2, in which there is generalized tonic rigidity without reflex spasms.

Both these types are mild, and usually occur after prophylactic antitoxin.

Type 3, like Type 2, but the stage of tonic rigidity passes into the stage of reflex spasms described above.

Type 4—splanchnic tetanus—in which the muscles of deglutition and respiration are involved early and generalized symptoms are slight or do not have time to appear. This form is very rare and fatal, and usually follows a visceral infection.

Type 5—cephalic (Kopf) tetanus—in which paralyses or irritation of cranial nerves, most commonly the seventh or oculomotor, appear early and generalized tetanus only later. This type usually follows wounds of the head or neck, and may be regarded as a form of local tetanus. If the wound is not severe the prognosis as a rule is good.

Diagnosis

"Lockjaw" is a good name for tetanus because it emphasizes the most significant early symptom. A small girl was told that if she cut herself between her thumb and first finger she would get lockjaw. A few weeks later she did this, and a few days afterwards, finding that she could not open her mouth, she told her parents she had lockjaw. It was only after she had been seen by three doctors, and after a good deal of delay, that her diagnosis was confirmed and treatment begun. The onset of painless stiffness of the jaw after a wound should always suggest the possibility of tetanus. Other important confirmatory signs in the early stages are: rigidity of the spine, with slight arching of the back so that the flat of the hand can be passed between the bed and the small of the back without difficulty, and almost painless but board-like abdominal rigidity, increasing when the trunk or limbs are manipulated or the patient attempts to move. The facial expression is also an important diagnostic sign.

Differential Diagnosis

From the early occurrence of trismus, tetanus has to be distinguished from local affections of the mouth such as an impacted wisdom tooth, tonsillitis, peritonsillar abscess, or glands about the angle of the jaw. All these conditions are painful, while the trismus of tetanus is comparatively painless; and this fact, along with a careful examination of the mouth and throat, is usually sufficient to solve the difficulty. Local tetanus may be mistaken for neuritis or arthritis, but, in the former, stiffness or twitching is more marked and pain is less. Cephalic tetanus with cranial nerve palsies has to be distinguished from Bell's palsy, polio-encephalitis, and meningitis, and the generalized form from meningitis and encephalitis also. Tuberculous meningitis may simulate it very closely. In these latter, diagnostic lumbar puncture may be necessary. When abdominal rigidity comes on before trismus, tetanus may be mistaken for acute abdominal conditions such as appendicitis or perforated gastric ulcer, but pain is a more pronounced early symptom in the latter.

Finally, the reflex spasms have to be distinguished from other forms of convulsion such as hysterical or epileptic fits and those of strychnine poisoning, in which trismus is a less marked feature. In these a careful history will often solve the problem.

Treatment

This is best considered under four headings: Antitoxin, treatment of wound, control of reflex spasms, and feeding and general management.

Antitoxin

When toxin is exerting its effect on the nervous system it is extremely doubtful if it can be neutralized by antitoxin; consequently if a lethal dose is so acting before antitoxin is given, this treatment cannot save the patient. Happily in most cases antitoxin can be given early enough to prevent the absorption of a lethal dose. The first need, therefore, is to flood the circulation with antitoxin as soon as possible after the first symptoms have appeared, so that toxin in the blood and lymph which is still accessible to antitoxin is neutralized and any further absorption from the wound prevented. A single large dose (200,000 I.U.) should be given by the intravenous route or, if this amount is not available, as large a dose as possible. In the case of wounds of a limb 10,000 units may also be injected into the subcutaneous tissues round the wound or deeply girdling the limb above the wound.

Repetition of Doses.—In cases with slight wounds I am very doubtful if anything is to be gained by giving further antitoxin With severe wounds 50,000 units should be repeated at weekly intervals or before any operation, until reflex spasms have ceased. It is difficult to see what is to be gained by daily repetition of injections, for it has been shown that antitoxin continues to circulate in large amounts for at least ten days after a big initial dose, and repeated injections are a worry to the patient and tend to increase spasms. To continue to give antitoxin after the reflex spasms have ceased and only tonic rigidity remains is a sheer waste.

Other Routes.—Antitoxin is also given intrathecally and cisternally, usually in combination with intravenous injections. and good results are claimed by some workers; the evidence. however, is conflicting. In my opinion nothing is gained and a great deal may be lost through the excitation of spasms by such procedures, and they are better avoided, particularly under Service conditions. If for any reason antitoxin cannot be given intravenously it should be given intramuscularly.

Before using antitoxin inquiry should be made as to previous serum therapy and for any history suggesting a tendency to allergy or anaphylaxis, and in cases of doubt desensitization should be carried out. If no contraindications are found the serum may be injected direct into a vein and need not be diluted or warmed. A solution of 1 in 1,000 adrenaline should be at hand in case of reactions.

Treatment of Wound

The wound should be touched as little as possible for an hour after antitoxin has been given. The aim should then be to convert an anaerobic into an aerobic infection by thorough drainage and removal of necrotic and infected tissue and foreign bodies. Wounds should be irrigated four-hourly with hydrogen peroxide through Carrel's tubes if for other reasons this is suitable, and dressings should not interfere with free drainage. It is thought that the practice of early excision of wounds, which was introduced in 1917, lowered still further the incidence of tetanus. The occurrence of tetanus may also be a factor in favour of amputation when this is considered for other reasons.

Control of Reflex Spasms

Tonic rigidity in itself is not dangerous; but reflex spasms exhaust the patient and stop respiration, and it is these which need to be checked. The rate at which they develop is the best indication of their approaching severity. If they begin within forty-eight hours of the first onset of trismus they usually increase rapidly both in frequency and in intensity. and may be very difficult to control. In such cases it is well to make preparations to deal with a sudden prolonged spasm should one occur without warning.

In mild cases and in the early stages before reflex spasms have begun, doses of potassium bromide up to 20 grains two-hourly or sodium luminal up to 1 grain four-hourly usually suffice for sleep and rest and to lessen the excitability of the nervous system. When reflex spasms come on they are most easily controlled by avertin or paraldehyde, given rectally as for basal anaesthesia. The dose of avertin should be between 0.07 and 0.1 c.cm. per kg. of body weight (estimated), and this usually stops spasms for from four to six hours. After this the dose has to be repeated, and it is sometimes necessary to give three such doses a day, and often two a day for some days consecutively. The effect in the individual patient and the frequency and severity of the spasms when they recur are the best indications for dosage. The dose of paraldehyde should be at least 1/2 drachm per stone dissolved in normal saline (1 drachm to 2 oz.). Both avertin and paraldehyde tend to produce cyanosis, and this should be controlled by warmed oxygen given by catheter or mask. Evipan intravenously is useful, particularly for sudden severe spasms which stop respiration completely; as also is nembutal, 1½ grains by mouth and repeated. Morphine and heroin should be employed sparingly, but are useful at times. Nitrous oxide and oxygen, chloroform, and ether are also occasionally of value, but if spasms are severe they cannot be inhaled. With all sedatives the risks of overdosage have to be weighed against the risks from the disease. If there is moisture in the lungs atropine should be given subcutaneously.

Feeding and General Management

Reflex spasms are excited by external stimuli of all kinds, and these must be reduced to a minimum. Patients should be kept as quiet as possible in a darkened room or at least be screened from others. The bedclothes should be cradled, and all necessary manipulations, such as feeding and the giving of injections, done while the patient is most deeply under the influence of sedatives. In severe cases a sister or orderly should be near the patient all the time. It is important to maintain strength by giving plenty of nourishing fluids and feeds whenever opportunity occurs. Glucose or cane sugar in water or weak lemonade, milky foods, egg and milk, broth, and bovril are all good, and the last two tend to make up any loss of chlorides from excessive sweating. When trismus is severe it is sometimes necessary to extract teeth before feeding is possible, and occasionally feeding by stomach tube is necessary. Avertin is often of great value in relaxing the jaw, and the attempt to feed should be made from one to three hours after the drug has been given. Feeding by rectal drip is also occasionally useful.

On active service the question may arise whether patients should be evacuated. The decision may be a difficult one and, apart from the wound, depends chiefly on the severity of the reflex spasms and the stage which the disease has reached. Patients who have not developed any reflex spasms four days after the onset or whose spasms have almost subsided can usually be moved with safety. Those who are developing them within four days or who are still having severe spasms should stay.

Complications and Prognosis

Pneumonia is a not uncommon and a fatal complication, and, if suspected, sulphapyridine should be given. Retention of urine occasionally occurs, and hyperpyrexia is usually a terminal event. The latter should be treated by antipyretics and tepid sponging. Sequelae of tetanus are rare.

In arriving at a prognosis the factors that have to be considered are: whether there has been active or passive immunization; the severity, degree of infection, and site of the wound; the length of the incubation period and period of onset; the age and physique of the patient; the presence of intercurrent disease or injury, loss of blood, or exhaustion; the severity of reflex spasms; and the conditions under which treatment can be carried out. An incubation period of more than seven days, a period of onset of more than two days, the presence of local tetanus, and a slight wound only, are all in favour of recovery. Other things being equal, the prognosis is better with wounds of the leg than with those of the head, neck, or arm. In war, intercurrent weakness from the severity of the wound itself, from haemorrhage, and from exhaustion has to be weighed against the beneficial effects of active or passive immunization.

The 34th annual meeting of the Medical Benevolent Society for the East and North Ridings of the County of York (including the City of York) was held in the rooms of the York Medical Society on Sept 30, Dr. C. H. Milburn of Harrogate presiding. The treasurer's report showed the society to be in a sound financial position, and it was decided to make further investments in Government securities. Since the last meeting two members had died, and sympathy was expressed with the relatives. One new member was elected. The annual grant to the dependants of an invalid member was renewed. The following officers were elected for the year 1942-3: Dr. M. Jacobs, Hull, President; Dr. Howard Jackman, York, President-Elect; Dr. G. F. Longbotham, Middlesbrough, Vice-President; Dr. D. Matheson Mackay, Hull, Hon. Treasurer; and Dr. W. W. A. Kelly of 92, Micklegate, York, Hon. Secretary, to whom inquiries may be addressed.

SOME OBSERVATIONS ON SENDING ASSISTANCE TO BOMBED TOWNS

BY

F. WILFRED WILLWAY, M.D., M.S., B.Sc., F.R.C.S.
Temp. Hon. Assistant Surgeon, Bristol Royal Hospital;
A.R.P. Officer, Bristol Royal Infirmary

I put forward these observations with some diffidence though they are written dogmatically. Many may be more experienced, but I have not had the good fortune to read their papers on the subject. If this paper provokes a discussion it will have served some useful function. Apologies are offered for the overuse of the "first person singular," but this is a personal report, and the observations and deductions are in no sense official.

In the winter of 1940-1 Bristol received its average share of air raids. I was active in all save one of these and learnt first-hand lessons. As the winter of 1941-2 approached we were all keyed up to face the bombardments that never came. Instead raids were made on smaller neighbouring towns, notably Weston-super-Mare and Bath. It is obviously possible to view a raid on a neighbouring city with considerable detachment. Such vision may be useful, and I had the good fortune to assist in the "good-neighbour policy" in all these raids. In each case we spent part of the time in the "blitzed city" and part of the time organizing in the "rescuing city." This was possible as the raids were repeated on the second night in each town.

On the whole the good-neighbour system worked well, but it is felt that many improvements could be made. I do not propose to detail what was done—this might be invidious—but the following commentary may be of interest. Admittedly some of it is painfully obvious, but most British cities found that it took actual bombs to drive the lessons home!

Communications

It is clearly vital to establish some sort of contact between the city needing rescue and the rescuer. It is true that rescue parties can be sent fully equipped and self-contained to a considerable degree, but usually fresh supplies, relays of helpers, etc., are necessary. As a busy voluntary hospital, heavily worked and with a war-depleted staff, we do not carry supplies sufficient for "self-contained" as opposed to "shuttle or circulating" rescue work. A fully self-contained unit would obviously need rations, a field kitchen, water, etc. None of this is available, nor is it considered desirable, though certain improvements along these lines could be made. In the case of the Weston raid, phone communication with Bristol was good though the line was sadly overworked (raid excitement) and messages were repeated unnecessarily—for example, a request for more sulphapyridine was separately phoned up by four officials.

In the Bath raids communication was bad. (This is written in terms of the hospital personally visited.) I arrived there at 2 p.m. on the day after the first raid. (I was then leading a surgical team under orders from the Group M.O.) We saw cases and operated till 12 midnight, staying at the hospital for the second raid. At 4.45 a.m. casualties were again arriving. Since leaving Bristol we had been unable to contact Bristol or the other Bath hospitals. The sole contact was the visit of a dispatch rider at 4 p.m. on the first day. We had then been there only two hours and were in no position to know what extra help might be needed, as the problem had only just been surveyed—e.g., some 60 casualties in an unfamiliar hospital with facilities for two teams to operate. At that time we were not *au fait* with the laundry position or the drug and dressing position.

At 6 o'clock on the morning of the second raid I returned to Bristol in my own car to obtain further aid. Clearly this was wrong. It should not be necessary to detach a surgeon to act as a dispatch rider. It is now obvious that when the dispatch rider called at 4 p.m., the aid I should have requested was the honour of a further inspection at, say, 10 p.m., when we would have understood the situation better. We should then have known enough to appeal for rations. The large team

I brought was deplorably fed, yet it worked for 24 hours except for a 4-hour break, and most of its members had been up and doing in Bristol for 14 hours previously. Good warm drinks and substantial meals are necessary for the nurses, doctors, and others in such circumstances.

It is suggested that the best system of communication would be as follows:

The Group Officer's nominee (subsequently termed the "Peripheral Group Officer") should visit the bombed city at the earliest possible moment after the raid. He should inform himself of the situation and establish a centre for his messages, probably at the largest hospital, definitely at any hospital able to telephone. He then phones his opposite number in the rescuing city or sends in his dispatch rider (who often could phone from just outside the city, saving time) and makes his wants known. This shuttle service must be kept alive until the work of "the incident" is over. The Central Group Officer can then organize all the help necessary. The Peripheral Group Officer must continually inform himself (not wait for information) how the hospitals in the bombed area are faring and their needs as they arise. For example, the destruction of a laundry at Weston created an immediate laundry problem. I initiated an immediate "lease-lend laundry system," with Bristol doing the wash. A functioning Peripheral Group Officer is in my opinion vital, to avoid overlap and duplication, often multiplication, of rescue services.

When Should Help be Sent?

When a small city is bombed there is no need to wait for a request for help. Surgical help should leave with the Peripheral Group M.O.'s team, the latter to be fully responsible for communication (detailed above). The hospital in the bombed city may be cleverly organized, but it will need help. If it is so staffed that it does not require help in an air raid, then it is over-staffed and is wasteful of man-power, and doctors should be requisitioned from it for military service! The policy of "waiting to be asked" is pernicious. Suitable help courteously offered will always be welcomed. It is not necessary to mention that the bombed cities alluded to asked for help and sensibly used it, and have sent subsequent thanks which were much appreciated. In one city that was helped, on the arrival of the rescuing team the whole resident M.O. staff of the hospital retired to bed—a sensible manœuvre.

What Type of Help should be Sent?

I have firm views on this subject, and they conflict to some extent with E.M.S. authority as stated in the "Red Book." However, I will venture to dogmatize.

1. The "Shock Troops" Team

The first help to be sent should be strong parties of medical students with a few sensible housemen. These I consider my shock troops—they are "go-anywhere-do-anything men." They will give a blood transfusion, take a blood pressure, shave a head, write notes (vital: I have seldom seen a "General" write a note), put out a small fire, act as stretcher-bearers, give simple anaesthetics, form a minor surgical team, and generally do the ten-thousand-and-one things that "proper doctors" seem to find beneath them. The supreme pull of the big city over the smaller is not in the greater excellence of its consulting staff but in the number of its medical students. Where possible I would include in the shock division that other salt of the earth, an almoner with her clerk. This division, warmly clothed* and well fed, should be on the road within 1¼ hours of news of "the incident." This news came in about 3 a.m. when there was a midnight raid 25 miles away, though I am convinced this information could be expedited. The "shock troops team" and the Peripheral Group M.O.'s team can well leave together.

2. Surgical Teams

The surgical teams that seem to be so beloved of the E.M.S. can well leave at a much later hour, say breakfast-time. They are not needed in the first few hours unless the stricken area has no surgeon at all (highly improbable), in which case a surgeon must leave with the shock troops. Most casualties can well do with a few hours' rest; the few "vitally urgent" cases can be dealt with by the local surgeons, who, having withstood the night's raid, will appreciate relief at 9 a.m. to see to their own homes, etc., but who do not want relief at 5 a.m. or 6 a.m.

The surgical team should consist of surgeon, assistant, anaesthetist, two nurses with theatre experience, and a sufficient number of medical students. The wise surgeon will pack his own kit; every surgeon will have his own fancy, but in air raids the best surgeon is the one who needs the least tools. I have a passion for taking razors (and a student to hone them) and nail-brushes; experiences of "hair like barbed wire" have developed this taste. I may here cavil at the usual theatre technique. The surgeon's clean washed hands are usually an improvement on the patient's wounds, while the ordinary theatre ritual is fantastically oversafe for a primary amputation or excision of wound edges of, say, a hole in the buttock. It is well to carry goods for one's own comfort—e.g., a theatre suit, gum boots, and a mackintosh. The visiting surgeon who bothers the visited hospital for these things is *not* helping—he's wasting time, energy, and tempers. Ideally, a surgical team should be relieved every 8 to 10 hours, otherwise efficiency will fall off. The provision of relief is the duty of the Peripheral Group M.O., whose job is always to view and review the problem, note how the work is progressing, and contact the centre. The surgeon in these teams should be a good general surgeon.

If one took the E.M.S. "Red Book" too literally the first duty of an M.O. at an E.M.S. receiving hospital apparently would be not to treat the sick but to notify them to someone else! Vide the following extracts:

> Page 17, para. 25.—"Whenever a patient with head injuries is admitted to a hospital the Regional Consultant must be informed immediately, if possible by telephone confirmed in writing, unless the patient has been admitted or transferred to a special centre, or has been visited by a neurosurgeon."
>
> Page 15, para. 20.—"Chest wounds, whether admitted direct or from first-aid posts, should not be retained at casualty hospitals, but should be evacuated as soon as possible to one of the special chest centres. If a case is not transferred at once the Regional Consultant must be informed immediately, if possible by telephone as well as in writing. A copy of the notification must also be sent to the Regional Hospital Officer, or in the case of the London Sectors to the D.G.E.M.S. at Whitehall. All penetrating wounds and severe crush injuries of the chest must be notified, but there is no need to do so in the case of surface wounds or simple fractures of the ribs."

Fortunately, so far as my information extends, England is full of doctors who read these regulations with a blind eye or swallow them *cum grano salis*. It is not disputed that they may be right and proper in "quiet periods" in a hospital; certainly they are *de trop* in a blitz period.

3. The Special Technique Team

By "special technique team" I mean those surgeons and assistants whose work requires trained assistants and, maybe, special instruments, etc. These teams may be found in neurosurgery, fractures, thoracic work, burns, and facio-maxillary work. Their use calls for much thought. I do not deny that many difficulties arise. There are various possibilities, and it is well to discuss them. The "quiet period" duties of these teams are clearly those of (i) attendance to routine duties; (ii) dissemination of information to their colleagues who practise in a more general way; (iii) holding demonstrations of technique, etc.

Their duties in a raid are less easily defined. Three possibilities emerge: (A) Should they remain at their base ready to deal with what comes to hand? (B) Should they await the summons of the Peripheral Group M.O.? (C) Should they tour the hospitals in the bombed city seeking their wounded amid the debacle? It is assumed that all these "specialists" cannot do both A and B. If they can, then there are far too many of these single-minded gentlemen, and they should be drafted elsewhere! In fact, the super-specialists should be organized, like the National Fire Service, on a drafting basis.

Possibility A is not ideal. In practice the patient does not often reach the right centre, and certainly not unharmed.

---

* Battle dress for shock troops is old clothes, a torch, pencil and pad, and a pair of dressing scissors.

With regard to possibility B, it is argued that the Peripheral Group M.O. will not be properly advised when to call for the special technique team and that delay may thus occur. This is surely a matter for education. (My own criterion of the "F.R.C.S. standard" is a "young surgeon who knows when he doesn't know.")

The third possibility (C), the "touring the battle-front" idea, raises interesting points—e.g., Who should tour? What should he take? The practice of the consultant touring alone is almost valueless. If he gives a little advice in the excitement of an air raid it may or may not get properly acted upon. If the consultant himself rolls up his sleeves and actually works, then he is working in strange surroundings minus his subordinates and cannot do the case justice. Further, he is likely to have a case that takes a long time, while the theatre door is crowded with fuming general surgeons waiting to lop off a leg or excise a wound.

In this connexion I put up two workable ideas for criticism.

(a) Let the consultant tour alone, *but* let him take an ambulance with him and let him seize the suitably wounded and *there and then* pack them off to his centre. Of course this will mean that the early bird will get the worm, for I must confess to having seen cases of multiple injury from air raids.* It is clear that the consultant cannot be "selecting winners" on the spot and curing them at the centre at one and the same time. It is assumed, however, that the rest of his team remain at the base, and in the absence of the General they carry on. If they are unable to act alone another consultant must move to the centre or base as its own consultant moves to the periphery.

(b) The consultant arrives fully equipped with his own team and tools and does the work on the spot. "Fully equipped," then, should mean "everything," or almost everything, the battle area supplying only a room. This method is expensive and it is slow. The necessary three-ton lorries would have to leave at the start of the incident. If their personnel was dispersed at all it would take a long time to collect. I once made plans with Brigadier Cairns for the Oxford Neurosurgical Service to relieve Bristol in this manner. We never tried the experiment, but my opinion is that if from Bristol an S.O.S. was sent at 12 midnight the lorries with relief might roll in about 12 noon the following day, probably later. Say 3 hours to get an S.O.S. out, 4 hours to collect and feed the team (one on week-end leave, one ill, one at a new address, etc.), and 4 to 6 hours on the road. Anyway, the E.M.S. has not provided fully equipped civilian teams in the sense alluded to—at least not in my region.

Probably choice *a* above is the better in view of present conditions. Choice *b* is certainly worth trial, and could be experimented with in one or two regions, and data collected.

4. Nursing Relief

This is important, and requires nice judgment and execution. A two-nights-running air raid is a heavy test of the usually busy, usually under-nursed general hospital. If to the admission of numbers of casualties be added minor bomb damage (windows blown in, no black-out, etc.) and noisy excitement in the daytime precluding rest, then the strain on the night nurses is heavy. We tried the experiment of exchanging units of nurses between the central city and the bombed town, thus providing a "quiet night." This needs much arranging and nice timing when all hospitals are working full out with minimal staffs. Two experiences in practice are related, and are instructive:

Twenty nurses were sent at 9 p.m. to the Weston General Hospital after the second night's raid (obviously no one knew if a third night's raid would occur). These nurses were courteously received and were distributed among the wards; during the night the local nurses were each given 4 hours off duty and their work thus lightened. Had a raid occurred the augmented staff could easily have shared the work. (A similar exchange of house-surgeons is desirable.) A similar party of 20 nurses were sent to another hospital, where the matron had already been advised to expect them. They were met on arrival, told they were not wanted, and sent back crestfallen to Bristol. What a lack of imagination and tact! The hospital in question did not even notify this action to the A.R.P. organizer, with the result that next day a bus was sent to fetch back nurses who had been returned the night before!

These contrary experiences merely confirm the need for good planning.

Summary

The salient features of the above observations may be summarized in the form of a time-table, thus:

Time	Duties of Central Bureau Officer at "University City"
Say 12 midnight	Incidents at Blankville (It is assumed that Blankville is 1 hour away by ordinary car)
00.30 hours	Notification received at "University City" of Blankville's blitz Immediate summoning of shock troops and Peripheral Group M.O.'s unit. Consideration: "Has Blankville surgeons enough or should a surgeon be sent *now*?"
02.30 hours	Departure of Peripheral Group M.O. and shock troops, all fed warm, transport fixed, etc.
03.00 hours	Warn special consultants and general teams to stand by for 8 hours
04 00 hours to 05.30 hours	(Depending on communications available to receive messages from Blankville.) Assess the degree of help which may be necessary
08.30 hours	Dispatch surgical relief teams *quantum sufficit*. Begin to plan for their relief S.O.S. N.B.—Information should be arriving constantly from the Peripheral Group M.O.
09.00 hours	Arrange for evacuation of beds in Blankville S.O.S. [And so on, depending on the seriousness of the air raid.]

PROPOSED NEW MEDICAL SCHOOL FOR LONDON

FOUNDED ON L.C.C. SERVICES

The establishment of an undergraduate medical school founded on the hospital services of the London County Council—which are by far the most comprehensive in the country and perhaps in the world—is proposed in a report which has been presented to the Council by its General Purposes Committee. The report is in the form of a statement of evidence to be given by the Council to the Interdepartmental Committee on Medical Schools recently set up by the Minister of Health and the Secretary of State for Scotland under the chairmanship of Mr. W. M Goodenough.

The new school would be established at one of the L.C.C.'s larger general hospitals and would utilize other hospitals and institutions as required. It is assumed that it would become an internal school of the University of London, which, in agreement with the Council, would provide the professional and teaching staffs. The arrangement would be similar to that obtaining at present between the British Postgraduate Medical School and the L.C.C. Alternatively, the Council itself might be responsible for the general direction of the school as in the case of the school for teaching in psychiatry attached to Maudsley Hospital. It is claimed that the experience which the L.C.C. has gained during the last 7 years in the case of the British Postgraduate Medical School (in which it has satisfactorily met any necessary modifications in the administration of Hammersmith Hospital) should be of great value in dealing with any new project on these lines. Any arrangement which the Council would make to extend medical education would be open to women students equally with men. On the financial side the Council would expect to be treated by the Government no less favourably than the voluntary hospitals and present medical schools.

The L.C.C.'s interest in medical education flows from its position as the major health authority for London, from the fact that it is the largest civilian employer of medical staff in the country, and from the facilities which its hospitals, numbering about 100, and its health services afford for a complete medical education. For some years past it has provided for the clinical teaching of undergraduate medical students by the affiliation of its general hospitals with voluntary teaching hospitals for teaching in obstetrics, fevers, psychiatry, venereal diseases, and other subjects. Up to the outbreak of war 11 of the medical schools were linked with 16 of the Council's "acute" general hospitals, in which classes and demonstrations were held, conducted by the resident medical staff, the Council's consulting staff, or members of the teaching staff of the students' medical school. Instruction in obstetrics has already been given at 10 of the L.C.C. hospitals to students from 9 of the London medical schools. Emergency courses of instruction in fevers are given at the fever hospitals, and, although the arrangements are not systematized, lecture-demonstrations to undergraduates are given at most of the mental hospitals. Plans are in hand for the teaching of psychological medicine in the Council's mental health services after the war.

---

* In these cases the zealous resident must notify (see "Red Book") three or four different consultant advisers and later divide the single patient among three or four different hospital centres. In the interests of logic the E.M.S. should appoint a multiple-injuries specialist and have done with it.

In so far as the Council's resources are used to augment the teaching in voluntary teaching hospitals (apart altogether from the proposal to set up the new school) the report calls for closer integration, particularly from the point of view of continuity of teaching. It is suggested that an advisory board be appointed for each combination of linked hospitals to make recommendations to the hospital authorities concerned for the appointment of teaching staff, the personnel of the board to consist of representatives of voluntary teaching hospitals and of the L.C.C., with whom representatives of London University would be associated. Teaching appointments should be regarded as including university chairs and readerships and the recognition of holders of whole-time posts as teachers of the university, while part-time consultants and specialists would be available for work in either voluntary or municipal hospitals, or both. If it is decided that a student after qualification but before registration should be required to hold a house appointment, the Council would consider a reasonable adjustment of its medical staffing arrangements to enable that to be done.

It is also considered that the service which the L.C.C. performs in the field of public health and social welfare should be brought more closely to the notice of medical students as a means of acquainting them with the wider aspects of social and preventive medicine, and the Council is prepared to offer facilities for organized instruction in the public health services and for the appointment of its staff as lecturers. Finally the report calls for better co-ordination of the facilities for postgraduate medical education in London, and the closer linkage of any new centres of postgraduate instruction with the British Postgraduate Medical School as the nodal point.

APPROVED NAMES FOR DRUGS

THE PHARMACOPOEIA COMMISSION'S POLICY

During the war the General Medical Council has published from time to time, on the recommendation of the British Pharmacopoeia Commission, lists of approved names for substances produced by British manufacturers, in some instances under licence granted by the Comptroller-General of Patents, Designs, and Trade Marks. The intention has been to recognize non-proprietary names which could be used freely by manufacturers, and thus to avoid the difficulties to medical men and pharmacists which result from a multiplicity of names for the ame substance. When any of the substances for which names have been approved have been admitted to the *Pharmacopoeia,* he approved name has been made the official title, but the ecognition of an approved name does not imply that the subtance will necessarily be admitted to the *Pharmacopoeia.*

The Pharmacopoeia Commission has now formed an advisory committee on nomenclature to assist it in the selection of approved names. Suggestions for suitable names will be nvited from the manufacturers interested in the production of a substance for which an approved name is required, and full onsideration will be given to the suggestions received. The Commission hopes that the approved names will be generally dopted, and would deprecate especially the introduction of new names for substances for which approved names have been published.

Principles of Nomenclature

The Commission has adopted the following statement of principles as a guide in the selection of approved names:

1. Names should, preferably, be free from any anatomical, physiological, pathological, or therapeutic suggestion. This pplies only to chemicals. Such suggestion cannot always be xcluded in the naming of biological products.

2. The accurate chemical name should be used if suitable; when it is unsuitable an attempt should first be made to form name by the combination of significant syllables from the cientific chemical name, and to include an indication of the potent element or constituent of a compound.

3. Names should be, in general, preferably of two, three, r at most four syllables.

4. Names should be distinctive in sound and spelling, and should not be liable to confusion with names already in use.

5. Names which are difficult to pronounce or to remember should be avoided.

6. The addition of a terminal capital letter or number should be avoided.

7. Names used in the current *United States Pharmacopoeia,* or adopted for the next revision, should be used either as principal titles or as synonyms.

8. Names used in the *British Pharmaceutical Codex* or in *New and Non-Official Remedies* should receive preferential consideration.

9. The following terminations, which are now well recognized, should be used so far as possible:

-ine (Latin -ina), for alkaloids and organic bases;
-in (Latin -inum), for glycosides and neutral principles;
-ol, for alcohols and phenols (-OH group);
-al, for aldehydes;
-one, for ketones and other substances containing the CO group.
-barbitone or -itone, for drugs of the barbiturate group;
-caine or -aine, for local anaesthetics.

Approved Names already Published

Certain names originally published as approved names have now been made official by the inclusion of monographs in *Addenda* to the *British Pharmacopoeia, 1932.*

Official Names: Third Addendum	*Other Names*
Bromethol	Avertin
Carbachol	Doryl
Hexobarbitone	Evipan
Iodoxyl	Uroselectan-B
Leptazol	Cardiazol
Mepacrine hydrochloride	Atebrin
Mepacrine methanesulphonate	Atebrin musonate
Nikethamide	Coramine
Phemitone	Prominal
Soluble hexobarbitone	Evipan sodium
Stibophen	Fouadin
Official Names: Fourth Addendum	
Pamaquin	Plasmoquin
Suramin	Germanin (Bayer 205)

New official names were given to certain substances included in the *British Pharmacopoeia, 1932,* and the *Addendum* 1936. For those names reference should be made to the relevant publications.

Approved Names	*Other Names*
Amethocaine hydrochloride	Decicaine
Cyclobarbitone	Phanodorm
Dienoestrol	Di-*p*-hydroxyphenylhexadiene
Diodone	Perabrodil
Diphenan	Butolan
Dithranol	Cignolin
Ethisterone	Ethinyltestosterone; lutocyclin, lutogyl; pregneninolone; progestoral; proluton C
Hexazole	Azoman; triazole
Menaphthone	2-methyl-1 : 4-naphthoquinone (Menadione *U.S.P.* XII)
Meprochol	Esmodil
Mesulphen	Mitigal
Pethidine hydrochloride	Dolantin
Pheniodol	Biliselectan
Pholedrine	Veritol
Soluble phenytoin	Epanutin; eptoin; sodium diphenylhydantoinate; solantoin; soluble dilantin
Sulphacetamide	Albucid

AWARDS FOR GALLANTRY

Mr. DENNIS OWEN CLARK, F.R.C.S., medical officer, mobile unit, Weston-super-Mare, has been appointed an M.B.E., and the G.M. and the B.E.M. have been awarded to Mr. HENRY COX and Mr. WILLIAM JAMES TYE, members of a rescue party, respectively. The citation in the *London Gazette* reads:

"During an air raid a house was demolished and five people were buried in the debris. Cox cut a hole in the floorboards and reached a woman, whom he released. He then came to a boy who was buried, lying on his back. Cox removed some debris by hand, freed the boy, and turning on his own back was able to drag him out. Tye then went into the tunnel to try to release a girl whose legs were pinned between boxes which were taking the weight of some tons of debris. This could not be moved without the risk of killing two other trapped persons. Although the whole structure was liable to collapse, Cox and Tye worked in relays, and, with their bodies, shielded the child from falling masonry and rubble, receiving cuts on their heads in so doing. Periodically, Dr. Clark went in the small opening to administer morphine and finally to perform the delicate operation of amputating the girl's leg, but this was found to be unnecessary, and after five hours she was released. Cox and Tye showed great courage and devotion to duty and the calmness and efficient demeanour of Dr. Clark inspired confidence in the victims and rescuers."

Reports of Societies

INFLUENZA EPIDEMICS: SOME CONUNDRUMS

In the Section of Pathology of the Royal Society of Medicine, on October 6, Dr. C. H. ANDREWES, F.R.S., delivered his presidential address, which he had entitled "Thoughts on the Origins of Influenza Epidemics," and propounded certain conundrums, with the broad lines on which the search for a solution might be made.

Of the periodical outbreaks of influenza the major ones were apparently due chiefly to influenza A, the virus isolated in 1933 and previously called "epidemic influenza virus"; others might be due wholly or partly to influenza B, the virus isolated independently by Francis and Magill in America in 1940, resembling the virus recovered earlier in being pathogenic for ferrets and mice but immunologically quite distinct. But along with the lesser influenza A outbreaks there occurred many cases of clinical influenza (called in America "influenza Y") which yielded no laboratory evidence that either of these viruses was concerned. A second conundrum was that influenza A viruses varied from one outbreak to another alike in rapidity of spread in the human population, in the ease with which they were established in ferrets, and in the ease with which the ferret-adapted strains could be got to infect mice. On the whole, the strains most infective and virulent for man had been those which most readily infected laboratory animals, but this relationship was by no means certain. Yet another problem was the whereabouts of influenza virus between epidemics. Influenza was only prevalent in Britain every other year, and when it came it was almost confined to the months January to March. The virus seemed to disappear for about 21 months out of 24, and this two-yearly rhythm roughly coincided with what was occurring on the European Continent and in North America. Swine influenza showed a somewhat similar regularity. It broke out in herds of pigs on the Middle West every winter and the virus disappeared every summer. Shope suggested that the virus had been seeded into the herd well ahead of the epidemic, but produced no disease until some trigger, such as change of weather or exposure to wet, fired off the epidemic. Did influenza virus persist in a masked or occult form, not necessarily, as in the case of the pig, in a worm in the lung? Again, there was the puzzling circumstance that some relationship was shown to exist between the immunity of an individual and the level of neutralizing antibodies in his serum, and yet potent antibodies diminished only to a limited extent his liability to infection.

The Search for a Solution

Dr. Andrewes then passed on to consider the broad lines along which he felt that a search for an answer to these various conundrums might be profitable. He discussed the supposed evolution of a virus on the presumption that the occurrence of influenza in an individual or community depended to some extent—not solely—on the grade of influenza virus; no doubt the specific and non-specific resistance of the individual or community, the weather, and social conditions also played their part. Nor did he suggest that influenza viruses of one outbreak would all belong to one grade; rather would the mean of the virulence grade of prevalent viruses vary from time to time. Two facts, when placed in juxtaposition, made him pause. This country was remarkably free from influenza for some years before 1890, but after the epidemic prevalence of the early 'nineties influenza had never fallen to anywhere near the 1890 level. Evidently an abnormal influenza epoch set in. The other fact was that in 1934, 1936, 1938, 1940, and 1942 influenza A, so far as could be judged from laboratory tests, was practically non-existent in England and Wales, and yet, as compared with the pre-1890 era, these had been years of relatively high prevalence of clinical influenza. Apparently waves of influenza A had been superimposed on an increased prevalence of something which was not influenza A. He was attracted by the hypothesis that the influenza virus had been regularly taking a heavier toll of human lives since 1890 than during the forty years before that, but that only in certain years had circumstances allowed it to attain that grade at which it became recognizable as influenza A.

Believing that the conception of a basic influenza virus suggested new lines of experimental attack, he went on to picture a human community in winter-time. A certain number of people might be carrying avirulent basic influenza virus, which spread by seasonal coughs and colds, and increased its grade of virulence by passage through a series of unduly susceptible persons until it caused symptoms. Three recent descriptions recorded influenza outbreaks in communities following upon epidemics of febrile catarrhs a few weeks earlier which had yielded no virus; the catarrhs might have played a part in the genesis of the influenza outbreaks. But a catarrhal outbreak must not be expected to precede one of influenza in every locality. A moderate view would picture epidemics of influenza as arising not from a single source or from latent infections of ubiquitous distribution, but from a limited number of scattered foci. When virulence had been speeded up locally, further spread by droplet infection could occur in the orthodox way. In such circumstances an increase in grade of virulence and spread through the community would take place or slow down according to the strength of various factors, including probably the average antibody level. Passage through very susceptible persons would heighten the grade of virus, and passage through the relatively immune would induce a fall. This idea of a gradation in properties of influenza viruses from basic virus to pandemic virus afforded a feasible explanation of the conundrums.

Possible Prevention or Control of Epidemics

Could such a picture assist in the prevention or control of influenza epidemics? The sequence of events leading to an epidemic was complex and might be interrupted at several different points. It might be attacked at its beginnings when virus of low grade was finding opportunity to spread widely. Improvement of aerial hygiene by better ventilation and other measures, if it decreased other respiratory infections, might make it difficult for influenza virus to get up its evolutionary momentum. Present methods of vaccination had only a limited value in protecting individuals, but influenza might quickly peter out if introduced into a closed community most or all of whose members had been recently vaccinated and whose antibody level was accordingly high; this was specially likely if the virus had not already attained too high a grade. Burnet in 1937 suggested that intranasal instillation of living attenuated virus might prove an effective immunizing procedure. The idea had theoretical advantages, but it was not yet known how to attain at will a safe and effective attenuated virus. It was rather like the lighting of small controllable fires in advance of a dangerous spreading conflagration, only to be done in the face of grave menace and if one was sure that the fire one had lighted would not get out of hand. Another suggested method of control for which good results had been claimed was local passive immunization of the respiratory mucosa by inhalation of atomized antiserum.

Should pandemic influenza recur Dr. Andrewes believed it would be found to be primarily a virus disease, and that the virus would be rather different from the influenza A virus of these times, though not unrelated to it. At the moment it seemed wise to learn all we could about the influenza which was with us, hoping to be better prepared to deal with the arrival of its fearsome relation. Before the 1918 pandemic there were a number of signs and portents in the form of abnormal prevalences of respiratory infections. He did not know that anyone had detected any grave epidemiological omens recently, but he would be a rash man who indulged in prophecies, hopeful or gloomy.

At the meeting of the Tuberculosis Society of Scotland held in Glasgow on Oct. 23, with Dr. C. Cameron (president) in the chair, Honorary Membership was conferred upon Sir StClair Thomson, who afterwards gave a lecture on "Tuberculosis of the Larynx: Diagnosis and Prognostic Value," illustrated with a lantern demonstration.

Correspondence

Air Disinfection

SIR,—With reference to your annotation entitled "A New Method of Air Disinfection" (Oct. 10, p. 431) may I be permitted to add a few remarks. We are of opinion in these laboratories that fundamentally chemicals exert their lethal action on bacteria by the same mechanism, whether the field of activity is in the test-tube or in the air. In estimating values, however, phenol coefficient and water solubility are pre-eminent in the former field, while vapour pressure and diffusion coefficient are additional factors of importance in the latter. When a bactericide is being tested in the air, rate and duration of action are noted. The two are incompatible in our experience, which, as a matter of fact, fits in with theory.

A germicide with a high vapour pressure has a rapid but evanescent action, while one with a low vapour pressure is relatively sluggish, albeit durable in its action, the test-tube phenol coefficient often coming but little into the picture. Glycols are examples of the former type of substance and hexyl resorcinol of the latter, resorcinol being an intermediate type. We found (*J. Hyg.*, Camb., 1940, **40**, 320) propylene glycol to be about as potent in the air as was carbolic acid, hexyl resorcinol being some 200 times as potent. Robertson found that 1 g. of the glycol in 50,000,000 ml. of air had under optimum conditions an effect (not pronounced), while we have observed a definite effect of hexyl resorcinol in a concentration of mist of 1 g. in 100,000,000,000 ml., and of resorcinol in ten times this concentration. These phenols are thus definitely "somewhat more effective" than glycols, and the contrast between their behaviour in air and in water is apparently again "extreme"—a not "unfamiliar" observation by other workers besides ourselves. At Portslade it is not felt that "no light has yet been obtained on its mechanism," and it may be pointed out that some of the phenols, as used by us, are odourless, non-irritating, and so far as test animals are concerned non-toxic.

It has to be confessed that we have really no knowledge as to the minimum effects sufficing to control cross-infection of respiratory diseases. It is possible that long before an inability to grow on agar plates is evident the bacteria in question have been so damaged that they are unable to cause infection. The arbitrary standard we set ourselves of a 90 to 95% kill within 10 minutes may be valueless or, on the other hand, unnecessarily severe. It is for this reason that the relative merits of different bactericides cannot be assessed until they are subjected to field tests, bearing in mind that they must have, or course, a low host–parasite toxicity ratio and other essential characteristics.

As regards mechanism of action—i.e., whether acting in mist or in vapour form—the probable answer is that bactericides may be lethal in either form. Few who have studied the subject would doubt this. But the size and number of germicide units in the air govern the collision frequency with the bacterium, so that it should theoretically have contacted 25,000 times the amount of germicide molecularly dispersed than when dispersed as a stable mist consisting of 1 μ particles. Hence we see why bactericides of high vapour pressure kill quickly, whether originally dispersed as mists or vapours. A quick kill of necessity calls for the employment of a larger amount of germicide than does a slower kill, and the question arises as to how far durability is to be sacrificed for rapidity of action. For example, 1,000 mg. of resorcinol painted on the floor of a chamber of 1 m.^{3} capacity will sterilize the atmosphere of the test organism in half an hour, and even when there is free access of the air to the outside will continue to do so for weeks. On the other hand, 1 mg. if mechanically atomized or heat volatilized will sterilize in 15 minutes, but will have lost practically all its activity within half an hour. The surface area of evaporation is very large in the latter case, but the reservoir of supply is small. If the paint be used in conjunction with the mist, the rate and durability of kill are influenced in the direction dictated by theory.

Finally, to consider solely resorcinol and propylene glycol: the choice lies between the use of 1 part of the former to kill in 15 minutes and 100 parts of the latter to kill in 5 minutes. Both procedures, including several others, are, in our opinion, "promising," but in these laboratories the glycols were discarded as germicide bases in favour of the phenols 4 years ago, and subsequent studies have strengthened our view of the apparent general superiority of the phenols.

Tuberculosis and Milk

SIR,—It is good to see Dr. C. O. Hawthorne again taking the field for pasteurized milk (Oct. 24, p. 494). Made with his usual graciousness his plea may carry conviction to hundreds of your readers and urge them to fresh efforts among their patients. Let them be wary, however, of a rebuff awaiting them. They may be told, and truly, that this summer pasteurized milk soured as quickly as the raw product. It was my own depressing experience to see a bottle of raw milk being taken to my grandchildren as their (pasteurized) supply "is so bad"! Taken up with the company responsible the fact emerged that the call-up of skilled workers meant inefficient processing of the milk and sterilization of the bottles. It was therefore of special interest to see in the Report on Tuberculosis in Wartime the recommendation that "specially skilled workers in pasteurization depots should be placed on the list of reserved occupations." Man-power is being saved by the new regulations concerning the delivery of milk. Should not equal attention be given to those who handle the milk before it reaches the retail distributors?

If confidence in pasteurization is once lost it will be regained with great difficulty. Dr. Hawthorne's medical missionaries should at least feel they "have their quarrel just" and that Government support is behind them. If the wartime situation does not allow an adequate supply of skilled workers for "processing," should we not ask for a stronger pronouncement from the Government concerning the necessity for home boiling?—I am, etc.,

Moor Park. ESTHER CARLING

Hepatitis

SIR,—I have read with interest Dr. Philip Evans's report (Oct. 17, p. 446) of an epidemic of hepatitis. The condition of infectious jaundice is probably more prevalent in London than is realized but remains unrecognized, while more frequent reports come from country districts because the cases are not divided between many doctors.

I was called early in September of this year to see a girl aged 23 who was working as an assistant in a day nursery in the North of London. She had a temperature of 101° F. and signs of mild sore throat. For four days she was running a temperature between 100° and 101° F., with no other symptoms except nausea and occasional sickness, when she took veganin tablets. On the fourth day I found a slightly enlarged firm spleen; the next day she developed jaundice with biliuria and clay-coloured stools, which were, however, not quite free from bilirubin. Two days later the stool turned normal again; biliuria disappeared, but the urine was still rich in urobilin for the following week; jaundice of the skin grew a little more intense. The temperature dropped to about 99° F. when the jaundice appeared. The liver was considerably enlarged for a couple of weeks, but was never tender to touch. The agglutination test made 10 days after was negative for typhoid and paratyphoid fevers and for the salmonella group

When I questioned the girl, who was quite intelligent, I learnt that a number of the children at the nursery had diarrhoea and in some of them she noticed pale stools, just as she had had. One child had developed jaundice. On further inquiry I was able to trace 3 more cases of jaundice from the nursery, which had been seen at the same period by a doctor. Probably more cases had no medical attendance at all. Another assistant at the day nursery, 18 years old, had to go to a hospital with pneumonia late in September. There she developed jaundice about a month after I had seen the other girl, this being quite a usual incubation period of this disease. She had pale yellow stools; later she developed granulocytopenia. The hospital doctor explained the jaundice as a toxic reaction to sulphapyridine treatment of the pneumonia. I am inclined to think the jaundice was an infectious hepatitis just coinciding with the pneumonia, and that severe leucopenic reaction was caused by the failure of the liver to "detoxicate" the drug. Though infectious jaundice generally takes a mild course it appears highly desirable that these cases should be made notifiable in view of the long convalescence, especially in adults. This outbreak was quite unknown to the medical officer attending the nursery.—I am, etc.,

London, W 9 F. MULLER.

Purpuric Type of Cerebrospinal Fever

SIR,—Dr. E. H. M. Milligan's letter (Oct. 3, p. 405) has called my attention to the earlier reference which he notes (Dr. I. S. Fox, Aug. 22, p. 218). Commenting on the case of fulminating purpura which he had described, Dr. Fox adds: "The illness is so fulminating and death occurs so early that complete investigation is generally not possible." Those who have had to deal with these tragic cases will readily endorse this.

There is one simple measure that I have never seen recorded which is worth doing because it may enable the diagnosis of massive bacteriaemia with meningococci to be made at once. During one of the most severe epidemics of cerebrospinal fever with which I had to deal and which occurred in Kunming, China, during the winter and spring of 1936-7, a child of 3 was brought to the hospital with an 8-hour history of severe fever. There was a moderately extensive purpuric rash, and a diagnosis of cerebrospinal fever of the purpuric type was confidently made. For some reason, in addition to a lumbar puncture, a blood film was taken and stained by the Romanowsky method. To our astonishment the film showed masses of meningococci. They were to be seen in every field clumped together in groups of 6 or 8 to some dozens. A number of other films were taken and all showed the same thing. During the course of the epidemic, although blood films were taken in cases without any purpuric rash, we were not fortunate in obtaining a similar positive result. Later, two further purpuric cases were seen, and in both of them meningococci were present in considerable numbers, though not as many as in the first case and they had to be searched for. All of these cases were fatal within 36 hours, and all were in young children.

At that time the sulphonamide drugs were only becoming known, and in the years 1938 and 1939, when Kunming was grossly overcrowded, scarlet fever and typhoid were the chief epidemics. Cerebrospinal meningitis was only met with sporadically, so that there was no opportunity to try the effect of massive doses of sulphapyridine (I left Kunming in July, 1939). I would suggest, therefore, that in any cases where there is a purpuric rash with high fever, and especially during an epidemic of cerebrospinal meningitis, blood films should be taken at once, stained by the Romanowsky or similar method, and examined for meningococci. In this kind of case every minute is valuable, and the sooner vigorous sulphapyridine treatment is instituted the greater the possibility of saving these desperately ill patients.—I am, etc.,

ALEXANDER J. WATSON, M.D., D.P.H.

Mildmay Mission Hospital, E 2.

Child Health

SIR,—Prof. Charles McNeil's review of 60 years' child health in Holland, Scotland, and England (April 4, p. 429), coupled with your leading article, prompts me to the expression of views that have long struggled for opportunity of outlet.

That "lack of knowledge on the part of doctors and nurses responsible for the welfare of infants before and after birth" is a root cause of our failure in this potentially fruitful field of medicine is undeniably true. Nor can one have anything but approval for Prof. McNeil's suggestions for the reorganization and emphasis on child health and welfare in our medical curricula. I would go further and add the following recommendations.

First, that the B.M.A., Ministry of Health, or some other responsible body with the necessary powers and facilities should appoint a medical committee to collect, collate, and co-ordinate the vast amount of knowledge we already possess on the subject of child health. On the basis of their recommendations the necessary changes required in medical education of medical students, nurses, health visitors, and child welfare workers could be carried out, and, in addition, some standardization of teaching and method could be adopted to counteract the present welter of confusion and contradiction between the advice meted out to the bewildered mother by her family doctor, health visitor, and clinic adviser. Secondly, that the co-operation of the Board of Education be invited and the advisability of including biology, elementary physiology, and hygiene in the teaching in all schools be urged. After all, it is ignorance in parents and grandparents that we ultimately wish to eradicate in addition to our own limitations as a profession. Only too often are our effort and advice frustrated by "grandma who had eleven children" (two of whom died in infancy).

Thirdly, it seems probable (indeed hopeful) that some form of State medicine will be evolved after the war. Surely the welfare of the child (and incidentally of the general practitioner) will best be served by bringing the better trained and educated G.P. into the public health or State-aided service as the child welfare clinic doctor. Even now the G.P. is no more ignorant of child health and infant welfare than the average assistant medical officer of health when he first takes over a baby clinic Indeed, he is often much more capable of giving good practical advice, and if Prof. McNeil's proposals are adopted he will be even more so. The practitioner is thus being brought back in his rightful place as the family physician and first link in the chain of medical supervision. The child is getting that continuity of treatment and observation that is needed for the best results, and the very real conflict between clinic and doctor is avoided. The doctor would have the facilities of the public health service at his command, health visitors, and laboratory aids, and the service of a consultant paediatrician could also be incorporated. Furthermore, each G.P. could see infants of all his own patients without extra cost to the family, and large overcrowded child welfare clinics with their attendant dangers would be avoided.

I am convinced that our present system of child welfare clinics run by the local health authorities is not producing satisfactory results. I myself (in peacetime) frequently had baby clinics of 60, 70, and 80, numbers being only the least of their disadvantages. There is a tendency inherent in all such clinics either to give away or to sell at reduced prices various artificial baby foods, which is, in my opinion, reducing the amount of breast-feeding instead of increasing it. A high proportion of breast-feeding can only be achieved by close observation and help from a well-trusted adviser in the last month of pregnancy and the first month of infancy. This the clinic doctor in the present system does not and cannot give. But small clinics run by family practitioners who have had adequate training would do much to reduce child mortality and morbidity and lay the foundations of a healthier and, I hope, happier people Finally, such a system would tend to offset the increasing absorption of members of the profession in purely or largely administrative work.—I am, etc.,

ERIC TOWNSEND,
Capt. R A M C.

Egypt.

Loneliness in Infancy

SIR,—I was delighted to read Dr. D. W. Winnicott's letter (Oct. 17, p. 465) on loneliness in infancy. It is a matter that has been exercising my mind greatly during the past year or two, during which the exigencies of war have removed me from my psychotherapeutic (analytical) practice and have required me to live in a hotel in a "reception area."

My work as an analyst had convinced me of the enormous significance of emotional distress in very early infancy—distress usually the result of being alone and helpless and without reassurance in times of discomfort or wakefulness in a still alien world. This kind of experience I had uncovered in maladjusted adults and seen as the source of a fundamental sense of insecurity, of the feeling of "the world against me," and of the fear of feeling and impulse, which so often characterize the neurotic personality. At the hotel I saw again and again these foundations being laid, not as the result of a physical separation of mother and infant, but by young mothers themselves (wives of officers), bursting with anxious enthusiasm not to "spoil" their babies, and convinced that the one way to avoid such "spoiling" was to leave them alone and untended from one feed to the next, no matter how desperately they might cry, and to cut down all physical and social contact and play to a minimum.

I maintain that "lethal" is not too strong a word to apply to such treatment, and lethal it has probably literally been in those not so rare cases of the baby found dead in its cot or pram, having, one surmises, cried itself sick and choked on its own vomit. But to keep to the psychological point of view, damage must result from such unnatural treatment. These infants (1) are left to deal alone and without reassurance with mounting rage and fear, which become beyond their power to control; (2) suffer too much deprivation and restriction of normal impulses; (3) are allowed no scope for the development of the first personal relationship with the mother. for which, as the late Dr. Ian Suttie has shown (*Origins of Love and Hate*, 1935), there is an inherent instinct in the infant and which lays the foundation of all future personal relationships.

The consequences of the first and second injuries (too great a demand and too much deprivation) are the development of (*a*) fear of feeling, inhibiting later emotional growth, and (*b*) excessive cravings or (if over-repression has had to be invoked to escape the intolerable situation) inhibition of normal impulses and a turning inwards instead of outwards for sources of satisfaction. The baby with finger or thumb in its mouth and the other hand fingering the hair or an ear is a characteristic result, and to my mind already reveals in these gestures the signs of future neurosis or maladjustment. The result of the third injury is a failure to lay sound foundations for future personal relationships, and the production of either a mother-fixed (excessive craving again) or an isolated personality incapable of deep outgoing affection.

What perplexes me is the anxiety of these young mothers, and the almost sadistic infliction of their maternity-nurse-derived principles on their defenceless babies. Is it that they themselves are the product of similar infant care and, as a result, lack the passionate impulses of love and compassion towards their babies which seem natural to the older generation of mothers? Victorian mothers cuddled their babies and demanded correct behaviour from their older children. Modern mothers are anxiously cold and remote in the handling of their babies and let their older children run amuck. Which method produces the better adult? Is there a connexion between world-wide war and the newer methods of baby culture?—I am, etc.,

Wem LAURA HUTTON.

Breast-feeding

SIR,—Dr. J. Gordon Mathias (Oct. 17, p. 465) says: "If Nature intended women to feed their young successfully, then they should adopt a more reasonable attitude and go on all fours"; and he asks: "Could there be a more awkward position for the suckling babe than the arm of its mother to sit on and a large breast to hold on to?" Hospital practice is to insist on the mother sitting up to suckle her child, and handbooks for mothers also recommend this as the method of choice. It is left for the mother to find out for herself sooner or later that it is much easier and more comfortable to lie at full length, with the infant lying beside her. Apart from the gain in comfort and convenience, this position also ensures regular rest periods, of which the nursing mother is much in need. Greater emphasis to mothers and to their relations on this need for rest might help to tide women over the special danger period for lactation—the few days after they get about again. The food and vitamin supply and the hygienic conditions of lactating women require as much consideration as those of pregnant women both from their doctors and from the general public. Prof. Charles McNeil, in his excellent alphabet of breast-feeding (Sept. 5, p. 271), claims the economy of the national milk supply as a special reason for encouraging breast-feeding. He forgets that at least 2 pints of cow's milk, or their equivalent in calcium, protein, etc., are probably required by the woman for each pint of milk secreted, as is recognized to some extent by the Ministry of Food in allowing 2 pints of milk daily for infants under 1 year and extra supplies of eggs also. Recent work indicates a raised requirement of vitamin B during lactation, which should be remembered as well as the commonly stressed need for vitamins A, D, and C.

Dr. Mathias appears to resent the possibility that mothers and babies may enjoy the process of suckling. Surely the fact that it is enjoyable should be emphasized, and the new-made mother should not be left unaware that to suckle her baby is, as Dr. Violet Russell says (Sept. 26, p. 377), "a pleasure and not an irksome duty."

I should like to emphasize Prof. McNeil's teaching that scanty lactation should be treated by shorter intervals between feeds. Too many mothers, nurses, and doctors regard the 4-hourly interval as sacred. Dr. Violet Russell urges the relaxation of the rules of regular feeding during the establishment of lactation, and the same relaxation is necessary if the milk supply falls off. A baby can be put on to 3-hourly or even 2-hourly feeds for a few days, and will return without any difficulty to 4-hourly feeds as the milk supply rises. I have known babies weaned, on medical advice, at the age of 2 or 3 weeks on the ground of "lack of milk," when suckling had been carried out only at 4-hourly intervals and on only one breast at each feed. Very few women could lactate with this inadequate stimulus. I certainly could not myself, though I have successfully suckled 5 babies up to the age of 10 or 12 months. The failure of mothers to breast-feed their babies is often associated with the doctor's advice to wean the baby. It is to be hoped that Prof. McNeil's alphabet of breast-feeding will help many doctors to give other advice.—I am, etc.,

DOCTOR'S WIFE

Treatment of Malaria

SIR,—I was glad to see that Prof. Warrington Yorke (Aug. 8, p. 167) disagreed with Sir Rickard Christophers's sweeping assertions regarding intramuscular injections of quinine at the meeting of the Royal Society of Tropical Medicine on July 23. At the African Hospital here, with over 300 beds and an average out-patient attendance of 260, between 30 and 50 intramuscular injections of quinine are given daily and we have not seen the terrifying results he mentions. The quinine solution is prepared locally. We have found that it shortens the course of the malarial attack and is a great saving in quinine —6 gr. daily as opposed to 30 gr. in an adult. We always give an injection of atebrin to blackwater fever cases on admission and to patients with malaria who have previously had blackwater fever, and we have never had cause to regret it —I am, etc.,

R. N. HALL,

Nigeria. Medical Officer i/c City Hospital, Kano

Dressing for Thiersch Grafts

SIR,—The following method of dressing Thiersch grafts may be of interest. Over the grafted area a piece of sponge rubber 3/4 in. thick is applied directly and fixed in position by means of parallel 1/2-in. strips of elastoplast spaced at intervals of about an inch so that light even pressure is secured. The sponge rubber is previously cut into a square or rectangle allowing about 1/2 in. overlap, and the corners and sharp edges are trimmed off with scissors. It is sterilized by boiling and the excess water squeezed out. No other dressing is applied and the part is left exposed to the air, if necessary under a cradle to prevent contact with bedclothes. The dressing is not interfered with for about 10 to 14 days unless there is a foul smell or excessive discharge around the edges. On removal complete healing is the rule. Even when mild sepsis occurred, which is difficult to prevent in a small proportion of cases when working under semi-tropical conditions, the grafts "took" well and often completely. While no originality is claimed for the details of this method, I have found it give far more satisfactory results than any of the other methods which were tried. The sponge rubber was obtained in sheets from the Dunlop Rubber Company, Bombay.—I am, etc.,

F. V. STONHAM,
Major, I.M.S

Scabies

SIR,—What is a "standard treatment"? Dr. G. H. Percival,[1] in his interesting article on the cure of scabies, criticizes my colleagues and myself for calling a course of three applications of sulphur ointment the "standard treatment"; he states that the standard treatment is one of six inunctions, and as his authority cites the publication by Walker and Percival.[2] We based our expression "standard treatment" on the advice given in the circulars on scabies officially published by the Ministry of Health and on the directions given in many reliable textbooks of dermatology. I am sure that all those concerned with the treatment of scabies would pay full attention to the carefully considered suggestions of writers of the calibre of Walker and Percival, but for Dr. Percival to state that a treatment becomes a standard one because he has published an article containing the suggestion is an assumption to which few others would aspire. Incidentally it has repeatedly been shown that with proper supervision even untrained personnel will cure very nearly 100% of cases of scabies with three inunctions of sulphur ointment, and even one application has been found by the health department of one of our larger cities to cure 90% of cases. To give six inunctions is a gross waste of medicaments and of man-power.

---

[1] Percival, G. H. (1942). *British Medical Journal*, 2, 451.
[2] Walker, Sir N., and Percival, G. H. (1939). *Introduction to Dermatology*, 10th ed., Edinburgh.

The advisability or not of disinfesting clothing, etc., is a question which is apt to become somewhat confused. I think that my experiments have shown that infection from inanimate objects, while occasionally possible, is unlikely to be one of the commoner ways of contracting scabies.[3] This does not directly affect the issue concerning disinfesting the belongings of patients known to be suffering from scabies. After adequate treatment with benzyl benzoate emulsion I have shown that the body is covered for at least twelve hours with an acaricidal film which will serve as an efficient disinfestor. If clothing and blankets do not often infect the normal body they are even less likely to reinfect a properly treated patient, and a painting with benzyl benzoate might be used prophylactically by anyone who is compelled to share a bed with a case of scabies. If Gordon and Seaton[4] had put a little benzyl benzoate on their rats' tails before applying the infested cloths they would have obtained a different result.

Dr. Percival alleges that in 1941 I advocated the omission of disinfestation but had more recently modified my views. Actually in 1941 I suggested that disinfestation might possibly be dispensed with but that further work was needed to clarify the issue. That work has now been done by a multitude of progressive medical officers of health and others. In a number of areas where the standards of diagnosis and treatment are high, disinfestation has been dispensed with without any deterioration in the results. Practical experience has shown that any possible increase in relapse rate (if this exists it is certainly under 1%) is fully offset by the great economy. In areas where contrary results have been obtained the fault has usually been attributable to bad diagnosis, as conditions other than scabies have been given incorrect treatment, with an unsatisfactory so-called relapse rate for "scabies."

Dr. Percival suggests that no technique is likely to be successful in 100% of cases This implies that sarcoptes is more difficult to kill in some patients than in others. With this view I completely disagree. I have found nothing to suggest that these parasites behave differently in different patients, and two, or at most three, applications of either sulphur ointment or benzyl benzoate, if properly used, will kill every parasite in every case of scabies. Even one application of benzyl benzoate emulsion will kill over 99% of the parasites. The lesions produced by scratching and secondary infection will, however, show considerable variation in their reaction to treatment, and their persistence often gives rise to the erroneous view that the scabies is still uncured. Incidentally, even if I found no live parasites after treatment I should not be entirely satisfied with a new method if I could only observe the patients for a fortnight. As with other parasites there is a great "wastage" with sarcoptes, and a month or six weeks may elapse before the mite population regenerates sufficiently to be easily recognizable.—I am, etc.,

Sorby Research Institute, Sheffield — KENNETH MELLANBY.

Prevention of Scabies

SIR,—The fact that the scabies epidemic continues almost unchecked in spite of weekly articles in the *B.M.J.* shows that there is something lacking in our approach. We still think of disease in terms of cure rather than prevention, and when we do consider prevention it is along the stereotyped line of catching cases early and inspecting all contacts. Our prevention does not begin until a family has actually got scabies; but to be effective we must start before that.

Scabies is very much commoner among the poor than the rich. If we could find out what gives the latter their relative immunity we should have gone a long way towards stamping out the disease. I was taught that scabies is not caught by shaking hands with people but by sleeping with them, the implication being that it is aetiologically akin to the venereal diseases. What my teachers failed to realize is that double beds are the rule in working-class homes, so that if one of the boys gets scabies his brother is sure to get it too. Many women dislike sleeping alone, and when their husbands are fire-watching they go to a friend's house, sleep with the wife, and put their children into bed with her children. Richer people do not do that; if they joined forces with another family they would all sleep in separate beds, and if these were not available they would consider their house full and not take in visitors.

Customs vary, and it would hardly be considered proper for the adjutant of a battalion to sleep with the second in command, but that would not have been at all strange in Elizabethan times, and Iago quite casually told Othello that he "lay with Cassio lately." Nor is it at all unusual to-day for working-men to share a bed. Recently I saw two civilians, strangers to each other, compulsorily billeted in Norwich and sharing a bed, both of whom had scabies, caught, as each supposed, from the other. The wealthier classes make a habit of taking off all their underclothes when they undress at night, but manual workers and their families usually put their pyjamas over their vests. That is a custom which can easily be changed, I find people are quite ready to accept the idea once it is put to them. Personal hygiene and social custom are the most important factors in the aetiology of scabies, and it is not good medicine to ignore them.—I am, etc.,

Norwich — FREWEN MOOR.

Treatment of Impetigo

SIR,—The article on wartime dermatology by Surg. Lieut. R. Workman Carslaw (Oct. 10, p. 420) again stresses the importance of discarding ointments wherever possible in order to conserve fats, and quotes Dr. R. T. Brain (Oct. 4, 1941, p. 492) that an ointment in the treatment of impetigo is inadvisable, as a film of grease retains exudates and sweat, which encourage the growth of organisms and irritate the follicles.

Having tried various time-honoured remedies—e.g., removal of scabs with olive oil or fomentations followed by ung. hydrarg. ammon. dil.—for impetigo, especially in children, with indifferent success, I have in the last few months treated a large number of cases by the method advocated by Lieut.-Col. J. H. Smith (Nov. 1, 1941, p. 640)—the application of liq. ferri perchlor. fortis without previous removal of scabs—and the results have been excellent. The spread of the infection has been stopped and the period of infectivity has been shortened very considerably. The action of the solution is that of an antiseptic and powerful astringent, coagulating albuminous fluids. It has no action on the unbroken skin and is non-poisonous to living matter (Hale White, *Materia Medica and Therapeutics*, 1942).

The advantages are simplicity of application—the treatment can be left in the hands of the patient—cheapness, and it avoids the waste in fats. The disadvantage is that the solution is painful on application and rather contraindicated for very young children. For these I have used 2% aqueous gentian violet as recommended by Dr. G. A. Grant Peterkin (Sept. 20, 1941, p. 422), but the treatment is more prolonged and the solution is mainly effective in the dry scaly stage. I have also used the liq. ferri perchlor. fortis solution in intractable cases of infantile eczema with very good results.

At a time when conservation of raw materials is so essential I would urge a wider application of this treatment in impetigo and the abandonment of the ointments so commonly used —I am, etc.,

Newcastle, Staffs — C. SIMPSON SMITH.

Classification of Nerve Injuries

SIR,—Lest he should rejoice too much I must point out that Dr. Walshe was included among the three unnamed complainants mentioned in my reply to Dr. Russell Brain; he was kind enough to write to me at great length when I was trying to make up my mind about these names for nerve injuries. If numbers meant anything I could dilate on the more numerous favourable letters that I have received, chiefly from medical officers in the Services who send patients here. These men, like myself, are more interested in clinical work than in laying waste your valuable space with verbal casuistry, and they discussed the classification and its clinical application rather than the three new words—or neologisms, as Dr. Walshe, oddly enough, prefers to call them. The three types could have been labelled "A," "B," and "C," like the vitamins (and combined lesions would have been represented with engaging implicity by combinations of these letters); but I thought, and still think, that, after the confusion that has prevailed for so ong in the nomenclature of nerve injuries, "neurotmesis," "axonotmesis," and "neurapraxia" were rather better in that hey were descriptive and reasonably accurate. It is to be noted that Dr. Walshe, even though he commands "the illimitable resources of our mother tongue," suggests no alternative names to cover all the conditions we are considering.

---

[3] Mellanby, K. (1941). *British Medical Journal*, 2, 405.

[4] Gordon and Seaton (1941). *Ann. trop. Med. Parasit.*, 35, 2.

It is good of him to mention "fibrin suture," for the use of this term shows that one does not use new words just for the fun of the thing, but only when they are needed. "Suture" is a fairly elastic word; anatomists, botanists, and zoologists use it for unions in which stitches play no part, and the significance of stitches in the surgical definition is no more than an indication that until recent times stitches were the only available means of joining sundered tissues. Its use in "fibrin suture" is as plain as a pikestaff; one does with a fibrin clot what is usually done with stitches, so why nvent a new word? As for being a terminological purist—I can make so such claim; for one thing, I never learned Greek. But like those who invented the words "telephone," "microphone," megaphone," and "loud-speaker," I want a name for a thing, and surely it is no offence if the term happens to be etymologically correct.

If Dr. Walshe reads again Weir Mitchell's case records he will find descriptions of all three basic types of nerve injury, But Weir Mitchell was denied the facilities we enjoy for direct examination of damaged nerves and he never essayed an unequivocal classification or gave names to the lesions. However, he did describe a striking clinical phenomenon and, Dr. Walshe not being there to stop him, called it by a Greek name, "causalgia." Weir Mitchell is remembered chiefly for this, and perhaps his work on ordinary nerve injuries would be better known had he made the classification that was almost within his grasp and christened the three types. It might have prevented the lamentable confusion that followed.

It is never too late to mend, and here is a classification which I believe to be fairly accurate and is undoubtedly useful; Dr. Walshe assails it only because the nomenclature is Greek, a language to which he is notoriously allergic. I am quite unrepentant, and am encouraged to be so by his choice of badinage rather than reason as his weapon.—I am, etc.,

Wingfield-Morris Orthopaedic Hospital, Oxford. H. J. SEDDON.

Working for a Salary

SIR,—Dr. H. G. Calwell (Oct. 17, p. 464), in his disagreement with Sir Beckwith Whitehouse's statement, quotes a series of pioneers who have achieved notable progress in spite of working or a fixed salary. A striking similarity in all the examples quoted by Dr. Calwell is that they were working in tropical diseases, presumably in places far from the distractions of civilization as found in our large cities, and that they were mostly no ordinary men, but of a type calculated to "come out strong" in any circumstances, so that I maintain that they provide the exceptions to Sir Beckwith Whitehouse's rule, and do not disprove it, as a series of examples from our public health and municipal hospital services might have done.

In my own experience of municipal hospital work in two big cities I have both felt the onset of mental sloth and stultification of effort indicated by Sir B. Whitehouse, and have seen men of promise enter the service and noted their deterioration into routine workers of mediocre performance and excessive outside interests. Observing this tendency in myself I hastily abandoned the security of a salary of fixed limits, a pension, and a "dead-end" job, and returned to voluntary hospital work, amid the derision of my late colleagues. It required an effort, which has since proved well worth the making, since I have just acquired an appointment in my specialty with facilities for teaching and research which I should not have obtained had I remained in the municipal service. The vast majority of us are all too easily influenced by environment, and should, therefore, seek out that which stimulates our efforts, which in most cases will not be found in the fixed-salary positions.—I am, etc.,

Preston. UNA M. WESTELL.

The Profession and the Services

SIR,—One feature of the "calling-up" of medical men for the Services, which has, as yet, excited little or no comment, is that affecting the voluntary hospitals. Many young surgeons working in these institutions have now been called up. I do not know the actual numbers involved, but in one hospital I know of four out of a staff of five general surgeons are now in the Services, and so far as one can judge their surgical work there is not, to put it mildly, arduous.

It would not appear that such a system is in the best interests of either the surgeons, their future patients, or the general public. As a team surgeon in the last war, I have a very lively recollection of the fine organization in the R.A.M.C. of that time, when mobile surgical teams were formed, each consisting of a surgeon, an anaesthetist, a theatre sister, and two R.A.M.C. orderlies. These teams continued work at their own hospitals and became familiar with each other's methods, etc., and were ready to proceed to any "sector" of the front where and when their services were required.

The advantages of such an organization are so obvious that one wonders why it should not have been applied, in principle at least, to the present situation.—I am, etc.,

GEORGE MCMULLAN.

Medical Planning Now

SIR,—I have just read Mr. H. J. McCurrich's letter (Oct. 24, p. 498). No sensible man has any illusions about politicians, but up to now it would seem that a great many of our profession have not realized and do not realize the urgent need for the doctors to go ahead with their plannings now. They have not realized that there is no choice between the present state of affairs and State medical services: the latter are already here. One has only to see the large number of well-equipped new county hospitals which have sprung up in the last few years, and the large number of county medical officers and clinics. No, the only choice we have is this: are the politicians going to run the medical services or are the medical profession? We should begin now to find men, medically qualified, to be trained in administrative work. Doctors are the only people who can understand doctors' problems, but they should be properly trained. It is no good putting a man into an administrative post merely because he thinks he would like to "have a stab at administrative work" and feels that is his *métier*.

The medical profession seem to have forgotten the lesson they should have learned when National Health Insurance was first brought in. I sincerely hope that there will be a great many more McCurrichs to see where the real question lies and what the real danger is.—I am, etc.,

Ledbury. GEOFFREY G. AIREY.

The Services

The King has made the following awards in recognition of gallant and distinguished services in Burma during the period Dec., 1941, to May, 1942:

C.B.E. (Military Division): Temp. Brigadier T. O. Thompson, late R.A.M.C.

O.B.E. (Military Division): Lieut.-Col. F. Oppenheimer, I.M.S.

D.S.O.: Temp. Col. G. E. MacAlevey, M.C., R.A.M.C., Capt. C. W. Elphick, R.A.M.C.

M.C.: Capt. H. O'Hara, R.A.M.C.

Mentions in Dispatches: Acting Col. J. Taylor, O.B.E., Major (Acting Lieut.-Col.) W. F. Lane, Major S. O. Bramwell, Capt. (Temp. Major) A. J. Martin, Capt. (Acting Major) M. S. Holman, and Capts. O. W. W. Clarke, P. W. Dill-Russell, A. P. Hick, R.A.M.C.; Acting Col. G. M. Moffatt, O.B.E., Majors (Temp. Lieut.-Cols.) C. S. Gamble and H. B. MacEvoy, Majors (Acting Lieut.-Cols.) A. E. Kingston and P. L. O'Neill, Major D. F. Eastcott, Capts. N. Ahmad, N. K. Mitra, and S. M. Basu, and Lieuts. A. Krishaswamy, G. M. Diwan, and R. S. Rao, I.M.S.; Assistant Surgeons F. J. Burby, C. E. Watts, and D. J. R. Snow, I.M.D.; Capt. S. M. Paw and Lieut. M. Nag, Burma Reserve of Officers.

CASUALTIES IN THE MEDICAL SERVICES

Wounded.—Acting Lieut.-Col. A. W. Gardner, R.A.M.C., Capt. N. J. P. Hewlings, R.A.M.C., War Subs. Capt. T. A. Shannon, R.A.M.C.

Prisoners of War.—Major L. Feinhols, I.M.S., Acting Lieut.-Col. M. R. Sinclair, O.B.E., I.M.S.

Missing.—Assistant Surg. A. R. Coshan, I.M.D.

Obituary

We regret to announce the sudden death on Sept. 30 at Dunham Massey, Cheshire, of Mr. **Frank Holt Diggle**, F.R.C.S., surgeon-in-charge of the ear, nose, and throat department of Ancoats Hospital, Manchester, and laryngologist to the Christie Hospital and Holt Radium Institute. Born at Heywood, Lancs, in May, 1886, he was educated at Rossall School and had a successful student career at Manchester, winning two scholarships and the prize in clinical medicine. He graduated M.B., Ch.B. (with honours) of Victoria University in 1909, and after resident posts at the Manchester Royal Infirmary and further surgical study in London obtained the Fellowship of the Royal Colleges of Surgeons of England and of Edinburgh in 1913. During the last war he served with the rank of captain R.A.M.C., and was surgical specialist to two casualty clearing stations. For his war service Holt Diggle was made O.B.E. in 1919. After returning to civil practice he was for a short time on the staff of the Birmingham and Midland Ear and Throat Hospital, and then went back to Manchester as surgeon to the Manchester Ear Hospital and aurist and laryngologist to Ancoats Hospital and the Manchester Union Hospitals. Later he became lecturer in applied physiology at the University. He was also laryngologist to the Royal School of Music in Manchester and to the Duchess of York Hospital for Babies. He joined the British Medical Association in 1921 and was secretary of the Section of Oto-rhino-laryngology at the Manchester Meeting of 1929, and published a number of papers on his specialty in these columns and elsewhere.

Dr. **George Smith** of Donaghadee, Co. Down, died in Ards District Hospital on Sept. 2 after a short illness. The elder son of Mr. E. C. Smith of Islandmagee, chairman of Antrim County Council, he was educated at Sedbergh and had farmed for some years on an extensive scale before entering the Queen's University of Belfast in 1922. He graduated M.B., B.Ch. in 1927 and held resident posts at the Royal Victoria Hospital and several other institutions. He proceeded M.D., B.Sc., D.P.H., and was for some time in the school medical services of Down Regional Committee. Since 1936 Dr. Smith had established an excellent practice in Donaghadee, and in addition was medical officer to the infectious diseases block of Ards District Hospital. In these spheres he was greatly beloved and esteemed by all with whom he came in contact. His untimely death in his 43rd year is deeply regretted, and warm sympathy is extended to his widow and two young children.

Dr. **Henry Willingham Gell**, O.B.E., of Church Aston Manor, Newport, Shropshire, died on Sept. 14 in his 86th year. His father was the Rev. J. P. Gell and his maternal grandfather was Sir John Franklin, the Arctic explorer. After obtaining his degree at Balliol College, Oxford, he entered St. Bartholomew's Hospital and qualified M.R.C.S. in 1885, taking the M.B. a year later. He then embarked on what eventually became a large practice in the West End of London, living in Hyde Park Square. In his earlier years Dr. Gell took a prominent part in the work of the National Health Society, both as lecturer and examiner, and wrote a popular little book, *Aids to the Injured and Sick*. He was for some time vice-chairman of the Paddington Board of Guardians and served for many years on the Metropolitan Asylums Board, presiding over many of its committees, more particularly the Ambulance Committee, where he took an active part in inaugurating the first motor ambulance service for the Metropolis. After his retirement from practice he went to live at Woolhampton Court, Berkshire. During the last war he gave voluntary service to the Reading War Hospital, for which he received the O.B.E.; towards the close of the war he undertook the treasurership of that hospital and set to work to inaugurate one of the earliest of the contributory schemes. Dr. Gell had been a member of the B.M.A. for 57 years.

We regret to announce the death of Dr. **William J. Candlish** of Bulwell on Sept. 18. Born at Birkenhead in 1886 he was educated at Bolton School and studied medicine at Edinburgh University. He had a distinguished career as a student, winning the medals for anatomy and pathology and the Wightman scholarship in clinical medicine. He qualified in 1912. After holding the resident post of casualty officer at Leicester Royal Infirmary and doing an assistantship he went to Bulwell, Nottingham, in March, 1914. During the last war he volunteered three times for the R.A.M.C. He was twice rejected; the third time he was accepted but was deemed indispensable. During this period he was carrying on a three-man practice single-handed and also acting as civilian medical officer to the troops stationed at Bulwell Hall, and latterly to the cadets of the Nottingham University O.T.C. Dr. Candlish was appointed medical officer to Basford Infirmary in 1919, and during a long association with that institution assisted its development into a modern hospital. For many years he served on the Nottingham Panel Committee and was a member of the Medico-Chirurgical Society, of the North of England Obstetrical Society, and of the British Medical Association. He was for many years an examiner to the General Nursing Council and medical officer to the Post Office. In 1939 he was appointed chairman to the Nottingham Medical Recruiting Board, a position he held at the time of his death. Candlish (writes H. J. M.) was one of those men whose capacity for work surprised everyone, and his enthusiasm was an inspiration to all. He ran a large general practice, and for years had allowed himself little time for leisure. Since his appointment as medical officer-in-charge of the Basford County Hospital he watched the development from chronic to more acute work, taking a particular interest in the emergency obstetric side. His interest in this branch of the work led him to take the Edinburgh M.D. at the age of 48, and three years later the Diploma of the Royal College of Obstetricians and Gynaecologists. He was a man appreciated not only for his skill but for his straightforwardness, kindliness, and tact—one had only to walk into the hospital to recognize at once that the right atmosphere was there. In consequence of this atmosphere the staff was with him heart and soul, and one realized that here was the right man in the right job. In his general practice, too, one felt immediately that the welfare of the patients always came first, and it was this will to serve to which he subordinated all else which eventually proved too much and precipitated his final illness. He will be sadly missed by a very large circle of friends.

After 58 years of active medical service Dr. **George Augustus Edward Roberts** died at Twyford, Hants, on Oct. 6, 1942, aged 80. Born on Feb. 2, 1862, at Ashley, Staffs, son of Dr. Thomas Roberts, he qualified at the Middlesex Hospital L.S.A. 1884, M.R.C.S. 1885, and D.P.H. 1897. After serving as house-surgeon to the Royal South Hants and Southampton Hospital he succeeded his father in practice at Twyford in 1887, and became M.O. to Winchester Guardians Committee. He was appointed M.O.H. to the Winchester Rural District Council in 1895 and held this post till Sept. 30, 1942—nearly 48 years. Largely owing to his efforts the Diamond Jubilee Hospital at Winchester, of which he was in charge, was built, and later the small-pox hospital. Dr. Roberts had been a member of the B.M.A. since 1887, and was also a member of the Society of Medical Officers of Health. He acted as honorary secretary of the Hampshire Local Medical and Panel Committees from 1912 to Dec., 1941, and for some years was a member of the Hampshire Insurance Committee. He published two papers in these columns: "Lead Poisoning from Home-made Wines" (1894) and "Lead Poisoning from Electrolysis of Water Pipes" (1906). Of wide experience, great kindliness, and sound judgment, he was always abreast of the times. A pioneer motorist in 1897 he drove till the year of his death. He began to use his own *x*-ray apparatus before the Boer War, and radium in 1909. He was also an early wireless enthusiast and held one of the first transmitting licences. A keen fisherman, none could tie a better fly; an amateur mechanic of no mean ability; all that came his way he took in his stride. When this war broke out in spite of his advancing years, he was M.O. i/c of Casualty Services. He served to the end. He leaves a daughter and two sons, both doctors.

Dr. **Walter Tyrrell Brooks**, who died in retirement at Swanage on Oct. 14, had been for many years a leading practitioner at Oxford, where he was physician to the Radcliffe Infirmary and for some time Litchfield lecturer in medicine. He was born in London on Oct. 25, 1859, and from King's College School went up to Christ Church and graduated M.A.Oxon. He studied medicine at King's College Hospital taking the M.R.C.S. and L.S.A. in 1882, and the M.B.Lond. with honours in medicine after winning scholarships at King's and holding a demonstratorship in physiology and anatomy. During the last war he served as officer-in-charge of the medical division of the 3rd Southern General Hospital with the rank of lieut.-colonel R.A.M.C.(T.F.). Dr. Brooks was for some time medical officer to Radley College, coroner for the University of Oxford, and administrator of the Orthopaedic Hospital at Headington. He was a member of the British Medical Association for many years and chairman of the Oxfordshire Insurance Committee in 1926-8. At the Annual Meeting of the B.M.A. at Bristol in 1894 he was honorary secretary of the Section of Medicine and its president at Oxford ten years later.

Universities and Colleges

UNIVERSITY OF OXFORD

In a Congregation, held on Oct. 15, the following degrees were conferred:

D.M.—*M. W. C. Oldfield.
B.M., B.CH.—M. G. Ellis, W. E. Hunt, D. S. Goldfoot, *L. J. Bussell, *W. H. H. Andrews, *R. E. B. Tagart.

*In absence.

An additional examination in medicine, surgery, and midwifery for the degrees of B.M., B.Ch. will be held at the end of March, 1943.

UNIVERSITY OF LONDON

It was reported at a meeting of the Senate, held on Oct. 28, that Sir Girling Ball had been elected Dean of the Faculty of Medicine for the period 1942-4.

UNIVERSITY OF EDINBURGH

On Oct. 23 Prof. J. H. Gaddum, Sc.D., M.R.C.S., successor to the late Prof. A. J. Clark in the Chair of Materia Medica, gave his inaugural lecture. The Principal of the University, Sir Thomas Holland, welcoming the new professor, remarked that he was the third in succession who had come from the Chair of Pharmacology in London University. Prof. Gaddum's subject was "The Development of Materia Medica in Edinburgh," and he devoted the first part of his lecture to an account of the work of all the holders of the chair from the time when it was separated from the Chair of Botany in 1768. He concluded by stressing the importance of the modern science of pharmacology to the student of medicine, who must understand the language of the laboratories well enough to get full benefit from the discoveries that were coming from them.

UNIVERSITY OF GLASGOW

At a graduation ceremony on Oct. 24 the following medical degrees were conferred:

M.B., CH.B.—*Douglas Jamieson, †N. R. Grist, †Zoë McF. Mackie, †L. H. Holroyd, †Edith E. Little, †Mary S. W. McCallum, †Jean A. Gibson, Jane E. Allan, W. M. Allan, A. Anderson, F. A. Ayles, J. T. Baird, Agnes D. Barr, J. Beattie, G. A. Bell, J. C. Beveridge, W. H. Black, T. A. S. Boyd, D. Brash, Annie C. Brown, J. K. Brown, W. McK. Brown, A. S. Browne, Anne H. Bruce, J. T. S. Buchan, R. A. Burnett, A. A. Clark, D. Clark, G. L. Clark, J. Colquhoun, W. M. Connell, A. H. Cook, N. R. Cowan, R. Dickie, Mary C. Fee, Margaret S. Ferguson, R. S. Ferguson, W. G. Ferguson, O. A. Finn, C. R. Forrest, A. Foster, C. C. Fowler, A. Fraser, C. Freed, T. Graham, T. E. Graham, Anne C. V. Greig, A. Grierson, J. McI. Hendry, R. K. Hinshalwood, Jean T. Holland, A. Hughes, T. Jack, J. R. Kenyon, Mary M. Kirkland, R. Lamb, Joan B. Landsman, Lilian Links, S. K. Livingston, D. F. McAlpine, Sarah Macaskill, A. K. McAusland, J. B. McBean, J. D. McCardel, H. R. F. Macdonald, J. A. Macfarlane, G. McHugh, A. B. MacLean, C. D. T. MacLean, H. I. MacLean, J. S. McLintock, J. McMillan, Violet C. I. Macnab, I. MacPhail, J. McSevich, W. S. Magowan, R. G. Main, W. G. Manderson, Margaret H. E. Martyn, Marjory B. Miller, J. G. Muir, W. J. Murphy, C. Naysmith, A. S. Nicolson, C. B. Noble, Ellen O'Hagan, F. O'Reilly, T. M. Paterson, Helen B. Phillips, Marie H. I. Reid, A. McQ. Robertson, E. McO. Robertson, J. A. M. Robertson, Constance A. C. Ross, J. S. Scobbie, J. K. Scott, G. B. Shaw, N. Shieff, R. W. Simpson, J. Smith, A. McG. Stevenson, G. T. Stewart, M. L. Thomson, R. M. Thomson, A. Tomney, E. W. N. Trounson, Barbara C. Tulloch, A. K. Turnbull, R. R. Waddell, Alison C. Wallace, J. M. Wallace, W. S. Wallace, R. G. Whitelaw, M. Mc Whittet, A. H. L. Wilson, I. R. Wilson, W. S. Wilson, A. P. Wright, H. B. Young, I. S. Young, S. Young.

*With honours. †With commendation.

D. Jamieson gained (*a*) the Brunton Memorial Prize as the most distinguished graduate in medicine of 1942; (*b*) the West of Scotland R.A.M.C. Memorial Prize for the highest aggregate marks in surgery, medicine, and midwifery in the Final M.B., Ch.B. examinations in 1942; (*c*) the Macewen Medal in Surgery for the highest aggregate marks in surgery in the Final examinations in 1942; and (*d*) the Stockman Medal for the highest aggregate marks in the professional examinations in materia medica and therapeutics and in medicine, excluding paediatrics, of 1942.

The Struthers Medal and Prize were awarded to Eldred W. Walls for the best original research or the best dissections or preparations relating to any part of anatomy.

W. G. Manderson gained the John W. Weir Prize for the highest aggregate marks in midwifery and diseases of women in the final degree examinations in medicine held during 1942.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At the annual meeting of the College, held on Oct. 21, the following officers were elected for the ensuing year: *President*, Mr. J. W. Struthers. *Vice-President*, Dr. H. M. Traquair. *Secretary and Treasurer*, Mr. K. Paterson Brown. *Representative on General Medical Council*, Mr. Alex Miles. *Convener of Museum Committee*, Mr. W. Quarry Wood. *Librarian*, Dr. Douglas Guthrie.

CONJOINT BOARD IN SCOTLAND

The following candidates, having passed the final examinations, have been admitted L.R.C.P.Ed., L.R.C.S.Ed., L.R.F.P.&S.Glas.:

R. W. Adam, J. F. Allan, H. A. Anderson, A. G. Annan, S. W. Bowden, W. H. N. Calwell, W. Candib, Y. N. Carayannopoulos, T. A. Christie, J. F. Couch, G. L. K. Crampton, D. V. Curran, G. H. Curtain, D. B. Donaldson, M. A. A. El Gayer, D. M. Forsyth, I. Gitlitz, I. G. Graber, Y. H. Karara, A. Klar, Kathleen M. McCusker, M. Macintyre, A. F. McInnes, Amy Mooney, A. S. Neilson, O. M. Neshamkin, D. J. M. D. Roper, A. R. C. Salem, W. J. H. Sayers, A. H. M. Shouman, J. A. Sinclair, B. M. Singh, A. W. Smith, B. Solomon, W. J. Stevenson, G. H. Vawda, R. Williams.

Medical Notes in Parliament

Pension Appeal Tribunals

Major MILNER asked the Minister of Health whether he could, if required, provide or make available a maximum of 50 medical men for the staffing of pensions appeal tribunals, either permanently or on the understanding that they could be released on short notice if urgently required for other purposes. Miss HORSBRUGH said that the pressure on the services of medical men was so severe that it would be difficult to supply those suitably qualified for this work in the numbers indicated. Any new obligation imposed upon the medical profession in war conditions would prejudicially affect other services. Major MILNER: May we take it that though it is difficult it is not impossible? Sir FRANCIS FREMANTLE: Is proper attention being given to the possibility of employing men who are discharged from high positions in different Services, who are men of great experience and could be used for this kind of work? Miss HORSBRUGH: Yes.

Dr. HADEN GUEST asked if it was not the case that a certain number of medical men in the Services were retired on account of age or of having held high rank for a certain period, and if there were not enough of these people fully to fill all the requirements of pension appeal tribunal purposes. He knew positively and could give Miss Horsbrugh a list of these people who would fill all these places. Miss HORSBRUGH said she hoped Dr. Guest would send her that list as soon as possible.

Discharge of Doctors from the Service

Asked the approximate number of medical men who on whatever grounds, had left the Army during the present war, Sir JAMES GRIGG stated that about 800 qualified medical men had left the Army during the present war. Major MILNER asked if it was not the fact that many of these medical men were quite suitable for utilization in other capacities in the Army, and that they were all qualified medical men who had been removed from the Army or had received their discharge, or something of that sort. Sir JAMES GRIGG said that a great many of them—more than half, in fact—had been invalided out.

Non-medical Commissions in the R.A.M.C.

On Oct. 20, in reply to Mr. H. N. Linstead, Sir JAMES GRIGG, Secretary for War, stated that pharmacists trained in zoology and physiology serving in the R.A.M.C. or newly recruited would be eligible for consideration for appointment to non-medical commissions in the R.A.M.C. They would normally be commissioned as second lieutenants, but would be eligible for promotion to war substantive lieutenant after 6 months. Selected officers would be eligible for promotion to captain as and when vacancies arose.

Progress in Rehabilitation

Mr. R. J. TAYLOR opened on Oct. 22 a debate on rehabilitation in industry. He said that between 1928 and 1938 accidents in mines and quarries numbered 1,600,000 and in all other industries 1,600,000. From 10% to 15% of the persons affected would be cases for rehabilitation. He praised the work done at Mansfield Rehabilitation Centre and said treatment there so helped spinal cases that the men were able to go back to their own work.

Mr. BERNARD TAYLOR spoke of the close co-operation between the safety and welfare officers appointed by two colliery companies in Nottinghamshire and the surgeon in charge of the Mansfield centre. The work was carried on even after a man re-entered the industry. Of 400 consecutive fracture cases among employees of the Bolsover Colliery Company, 389 of the patients returned to productive work and 378 to their pre-accident work. Those who could not return to the mining industry were turned over to the Ministry of Labour, which had facilities for training.

Mr. TOMLINSON, for the Ministry of Labour, said the process of restoring lost muscle tone and the full functions of the limbs and of maintaining general health and strength should begin as soon as the patient's condition permitted, and should be a continuous process. When restoration in the medical sense had been achieved, social and industrial experts, in consultation with the medical experts, should decide whether the patient could return to his former occupation or to what occupation. In the Emergency Hospitals Scheme many orthopaedic centres had been established with a full range of facilities. Other hospitals had been noted for fracture cases. At least a skeleton service was available. The people responsible for the work at Roehampton had been pioneers in a vital cause. Twelve months' experience had been gained of the scheme introduced by Mr. Bevin in Oct., 1941, for training and resettlement of disabled people. A greater scheme might emerge from this. The psychological effect of interviews in hospital which brought home to the individual the possibility of returning to work was great. The scheme had been extended to all types of industry, and up to the end of August 41,000 people had been interviewed. Of this total about 29,000 had been placed in or found employment. Of 600 blind persons interviewed, 200 had been placed in employment other than that previously deemed suited for the blind. Many blind persons were to-day doing jobs in engineering shops. Treatment and training centres at Exeter and Leatherhead had been taken over by the Ministry of Labour.

Venereal Disease

Mr. BARSTOW on Oct. 22 asked whether the Minister of Health proposed to take steps to enforce compulsory notification of venereal disease, having regard to the increase in these diseases throughout the country. Mr. BROWN replied that he was considering what action could most appropriately be taken to check the spread of venereal disease. At present he doubted whether compulsory notification was best calculated to secure this object. He further told Colonel Heneage that he was aware of the difficulties of dealing with carriers of venereal disease. He had under urgent consideration the most effective methods of dealing with them.

Service Discharge for Tuberculosis

Sir WALTER WOMERSLEY said on Oct. 22 that of the total number of men invalided out of the Forces from the outbreak of war until the end of Sept. last 5.8% were discharged on account of tuberculosis. Of the claims made in respect of this disability rather more than 70% had been allowed.

Small-pox

The Secretary of State for Scotland was asked whether he was aware that there were errors in regard to the vaccinal condition of 5 out of the 33 cases of small-pox which occurred in Glasgow, and whether he would insist that the Department of Health for Scotland ascertained all facts more accurately in future. Mr. JOHNSTON said he was aware that subsequent investigation elicited further information about the vaccination history of certain small-pox patients. The original statements of the patients and their friends were checked by further inquiries as pressure of work more essential to the control and eradication of the disease permitted. At any given date, the Department of Health for Scotland could only ascertain from the local authority concerned the position according to the evidence then in the authority's possession. Asked whether, in view of the serious risks likely to result from the failure of ship doctors to notify cases of small-pox on vessels arriving in this country from oversea ports, as happened at Glasgow on May 29 last, he would consider the desirability of issuing a special memorandum to such doctors on the diagnosis of that disease, Mr. Johnston said that this suggestion would be considered in current discussions between the Health Departments and the Ministry of War Transport regarding measures of protection against seaborne infection.

Notifiable Diseases

Mr. BROWN has furnished the following statistics of the incidence in Great Britain during the past 5 years of diphtheria, cerebrospinal fever, measles, pneumonia, and whooping-cough. Mr. Brown remarked that only certain forms of pneumonia were notifiable, and compulsory notification of measles and whooping-cough was not introduced till late in 1939.

Year	Diphtheria	Cerebro-spinal Fever	Measles	Pneumonia (Primary or Influenzal)	Whooping-cough
1937	61,341	1,140	—	55,896	—
1938	65,008	1,288	—	45,160	—
1939	47,349	1,506	—	42,307	—
1940	46,260	12,767	409,593	47,877	53,630
1941	50,935	11,073	409,531	50,921	173,319
1942 (First six mths	20,340	4,252	100,762	27,528	36,861

Admission to Medical Schools

Sir E. GRAHAM-LITTLE asked on what the Minister of Health based his allocation of quotas of admission of students to individual medical schools. Mr. BROWN said that by arrangement with the Minister of Labour quotas for male medical students at each medical school were based normally on the average yearly admissions over the three years 1936 to 1939. In certain cases a variation to suit local conditions was allowed on the advice of the Chief Medical Officer of his Department after considering the representations of the school authorities. Quotas for women students were similarly fixed on the basis of the average admissions for the three years 1937 to 1940. Where the number of male applicants fell short of the quota for men, no objection was raised to the admission of women to make up the deficiency if the school so desired. He had no authority to make a quota conditional on acceptance by the school concerned of a certain proportion of women students. That issue was under consideration by the Committee on Medical Schools.

Incidence of Industrial Dermatitis.—On Oct. 20 Mr. BEVIN told Mr. Pritt that cases of industrial dermatitis notified to the Ministry of Labour in 1941 and 1940 numbered 7,291 and 4,744 respectively. A total for this year was not available. Posters were widely exhibited in factories where there was a special dermatitis risk, and preventive measures were also promoted through medical and welfare supervision, supervision of washing arrangements, and in other ways.

Rural Doctors' Petrol.—On Oct. 20 Mr. SCOTT asked the Minister of Fuel and Power if he was aware of the inconvenience suffered by doctors in country districts by the present petrol restrictions and the consequent danger to public health, and if he would consider depositing extra petrol coupons with the local police, to be issued to doctors and ambulance drivers in cases of emergency when their own supply was exhausted. Mr. LLOYD: In consultation with the British Medical Association arrangements have been made to secure that no doctor shall be hampered by lack of petrol for his essential professional journeys. I am not aware of any failure of these arrangements, but I shall be happy to consider any case of which Mr. Scott will give me particulars.

Notes in Brief

The number of persons in Great Britain insured under the National Health Insurance Acts at the end of 1940 (the latest date for which the information is available) was approximately 22,300,000.

Mr. Bevin is advised that it is not necessary to make industrial dermatitis a notifiable disease.

A scheme has been framed for financial assistance on demobilization to men and women who were pursuing courses of study at universities before being embodied in the Forces.

According to sample statistics taken earlier this year about 1% of recruits examined under the National Service Acts are rejected on account of pulmonary tuberculosis.

Medical News

At a meeting of the Committee of Management of the Medical Insurance Agency on Oct. 28, the Chairman, Sir Humphry Rolleston, Bt., G.C.V.O., K.C.B., M.D., resigned this post, which he has held since 1924 continuously. A resolution expressing high appreciation of his long and valuable service was passed by the Board and ordered to be entered in the minutes. Sir Robert Hutchison, Bt., M.D., was appointed as his successor.

The Pharmaceutical Society of Great Britain has arranged a lecture on "Nutrition," to be given by Prof. J. C. Drummond, scientific adviser to the Ministry of Food, at Friends House, Euston Road, N.W., on Thursday, Nov. 12, at 2 30 p.m

From Nov. 8 to 22 inclusive a National Exhibition of Soviet Life in War and Peace will be held at the Wallace Collection, Hertford House, London, W. During the fortnight a comprehensive programme of events has been arranged. Among them is an address on Nov. 12, at 1 p.m., by Dr. Joan McMichael, who will speak on the medical services in the Soviet Union. Films will be shown on various aspects of Soviet life throughout the fortnight at 4 p.m. every day.

A sessional meeting of the Royal Sanitary Institute will be held at the Royal Beach Hotel, Southsea, on Saturday, Nov. 14, at 10.45 a.m., when papers will be read by Dr. A. G. Shand on "Diphtheria Immunization, with Special Reference to the Work of a Mobile Clinic," and by Dr. J. W. Thornton on "Wartime Disinfestation."

A lantern lecture on "The Future of Health and Hospitals from an Architect's Point of View" will be given by Mr. Charles E. Elcock, F.R.I.B.A., in the Physics Lecture Theatre, Royal Fort, University of Bristol, on Friday, Nov. 27, at 2.30 p.m., under the auspices of the Bristol and District Divisional Hospitals Council.

Among its other activities the Free German Institute of Science and Learning arranges courses of lectures on scientific and medical subjects. The programme for the period ending Dec. 15 can be had from the Secretary, 16, Buckland Crescent, N.W.3.

Dr. W. R. Wooldridge, president of the National Veterinary Medical Association, has announced the formation of a Veterinary Educational Trust to raise and administer funds for providing better facilities for the education of veterinary surgeons.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* there was a rise of 25%, 1,146 cases, in the incidence of measles. The other large variations were increases in the notifications of scarlet fever, 90, and acute pneumonia, 67; and decreases in the incidence of whooping-cough, 65, and diphtheria, 20. The first case of typhus reported in the country for thirteen years occurred in Bournemouth C.B.; the last case was in Sunderland C.B. during 1929.

The rise in measles was general throughout the country, but was most pronounced in the adjacent counties of Yorks West Riding, Lancashire, and Cheshire; the notifications in these counties were 523, 170, and 120, respectively, higher than the totals of the preceding week.

Scarlet fever has been on the upgrade for eight consecutive weeks, the number of weekly notifications being larger than at any time since the autumn of 1937. The only variation of note in the incidence during the week reviewed was an increase of 33 cases in Essex.

Exceptions to the general decline in diphtheria were the rises in Staffordshire, 25, and Durham, 22. The largest fall was that of Lancashire, where there were 41 fewer cases.

The trend of whooping-cough, although decreasing for the whole country, fluctuated within the counties. The largest of these variations in the incidence was a drop of 46 in London.

The number of cases of dysentery has fallen by one-third during the past month, but the incidence is still at a high level. During the week there was a fresh outbreak in Hertfordshire, 28 cases (Bishop's Stortford U.D. 22, Hertford M.B. 4, Hertford R.D. 2). An increase of 9 was recorded in the totals for Norfolk, 27 cases, and Northumberland, 14. In Yorks North Riding notifications fell from 30 to 11, and in Wales from 46 to 15.

In *Scotland* there were substantial rises in the notifications of measles, scarlet fever, and dysentery. The rising trend of each of these diseases was due mainly to the experience of only one town: Edinburgh experienced a rise from 63 to 113 in the number of cases of scarlet fever; in Paisley measles went up from 68 to 120 cases; Dundee with 36 cases of dysentery had almost half of the total notifications.

In *Eire* an increase was reported in the notifications of measles, diphtheria, scarlet fever, and whooping-cough. Whooping-cough was confined to two areas: Dublin 41, and Co. Clare (Kilrush R.D.) 17. Almost half the recent cases of measles have been recorded in Co. Mayo (Castlebar R.D.). The outbreak of poliomyelitis persists, and the hope that with the onset of the colder weather the incidence would drop sharply has not been realized. Since July there have been 137 cases, with 34 deaths.

Diphtheria Immunization

Out of the 1,440 local authorities in England and Wales, 685 have reported to the Ministry of Health that up to the end of June 50% or more of the children aged between 5 and 15 had been immunized in their areas.

Small-pox

There have been no fresh cases in the Methilhill outbreak, Fife, but a suspected case, a contact from Methilhill, has been reported in the Larkhall district of Lanark. The movement of contacts has caused concern and, according to the Press, almost led to a strike at the local colliery because contacts were allowed to return to work. According to statements in the Press on Nov. 3, 2 cases of small-pox have been reported in Edinburgh and 1 in Belfast.

Returns for the Week Ending October 24

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 2,619, whooping-cough 984, diphtheria 971, measles 6,803, acute pneumonia 659, cerebrospinal fever 66, acute poliomyelitis 25, dysentery 177, paratyphoid 7, typhoid 12.

From a study of 706 State nurses in 6 different municipal hospitals, D. R. Hastings and D. G. Behn (*Amer. Rev. Tuberc.*, 1941, 44, 681) conclude that the extent of tuberculosis and of tuberculin-positive reactors is no higher among girls about to enter training than for any similar group of young women. The infection rate, as measured by a change from a negative to a positive tuberculin reaction, is about 11.6% higher for those nurses who spend a certain portion of their training period on tuberculosis service. At the beginning of training 96.3% of the girls had completely negative *x*-ray films. At the end of three years of training the figures were 93.3% for nurses on tuberculosis service and 94.8% for those on general nursing. Tuberculin-positive nurses, the authors point out, are much less likely to develop tuberculosis during training than are tuberculin-negative nurses.

No. 41

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Oct. 17.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1942					1941 (Corresponding Week)				
	(a)	(b)	(c)	(d)	(e)	(a)	(b)	(c)	(d)	(e)

Annual death rate (per 1,000 persons living)			12·2	13·4	‡			11·1	11·0	‡
Live births	6,033	727	945	377	252	5,153	460	892	304	210
Annual rate per 1,000 persons living			19·5	25·2	‡			18·1	20·2	‡
Stillbirths	202	18	44			207	11	36		
Rate per 1,000 total births (including stillborn)			44					39		

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes paratyphoid A and B for Northern Ireland.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE No.—B.M.A. and *B.M.J.*: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent, London*; SECRETARY, *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh

QUERIES AND ANSWERS

Anaemia in Young Adults—Dietetic?

Dr. G. D. SUMMERS (Lincoln) writes: I was interested to read Mr A. J. Hobson's letter (Oct. 17, p. 467). I can report a dietetic anaemia of similar symptoms locally among women and girls between ages 11 and 31. I first noticed it 6 months ago, and increase in numbers is progressive. A patient aged 40 with a similar anaemia had given a pint of blood 7 weeks previously. I suggest as causes: (1) Mother feeds up the men and boys at the expense of the girls and herself. (2) The great lack of eggs locally since they were collected for the larger towns, nothing coming back to the countryside to replace them. Parsley is said to be good for one. Can any of your readers tell me whether it contains iron or any vitamin, please?

Infra-red Radiation for Migraine

Dr OLIVER SPRINGER (Glasgow) writes: In reply to Dr. E. V. Claydon (Oct. 17, p. 472) I do not think that the case mentioned was a true migraine, as any such patients who have been under my care, and who have been complaining about the usual sensory phenomena, have never reacted to infra-red radiation. I have, however, obtained excellent results, in cases of recurrent headaches, by treating the fibrositis at the back of the neck with heat and massage. I have never had any ill effects from the application of infra-red radiation to my head or that of any of my patients.

Aspirin for Asthma

Dr. H. THISTLETHWAITE (Sedbergh) writes: Dr. W. Lees Templeton (Oct. 24, p. 503) appeals to logic to justify homoeopathic doses (of aspirin). I have had some training in logic, but can construct no valid syllogism from the premises given. The argument appears to stand thus: 10A causes X in B; 2A relieves X in C; ∴ 2A will relieve X in D, E, F, and G, not to say in B also. As I once unintentionally practised this argument upon an A-sensitive patient with a proprietary mixture containing 1¼ gr. of sodium salicylate per dose I am in a position to state that the only possible conclusion in my logic is that even 1¼ A causes X in B. I hope I make myself clear.

Income Tax

Pension under Superannuation Act

"D.P.H." is in receipt of a pension granted by a local authority under the Superannuation Act and has claimed exemption from tax on it on the ground that his retirement, and therefore the grant of the pension, was occasioned by permanent impairment of health attributable to work in connexion with civil defence and supervision of military accommodation. The inspector of taxes has refused his claim.

⁂ We cannot advise "D.P.H." to appeal against the inspector's decision. Such a pension does not fall within the various classes of disability pensions specified in Sec. 16 of the Finance Act, 1919, nor is it paid by the Ministry of Pensions in respect of war injury. The war has accelerated the grant of the pension, but its nature and source are unaffected.

Pension for Military Service

"Ex-R.A.M.C." has been discharged owing to chronic illness contracted while on active service. He is at present being paid an allowance by the Ministry of Pensions at the rate of £195 per annum. Is this allowance subject to United Kingdom income tax?

⁂ The question is governed by section 1B of the Finance Act, 1919, which provides that "(*h*) retired pay of disabled officers granted on account of medical unfitness attributable to or aggravated by naval, military, or air force service . . . shall be exempt from income tax." The section provides further that "where the amount of any retired pay or pension to which the section applies is not solely attributable to disablement or disability the relief [i.e., the exemption] shall extend only to such part as is certified by the Ministry of Pensions . . . to be attributable to disablement or disability." Presumably "Ex-R.A.M.C." will be entitled to the exemption.

LETTERS, NOTES, ETC.

A Light Trailer Ambulance

Dr. T. J. T. WILMOT (Louth, Lincs) writes: Dr. K. Vernon Bailey's letter (Sept. 5, p. 296) raises a question that is of great importance throughout the country. Ambulances of many types have been improvised everywhere, but a means of dealing with stretcher cases before ambulances are available is likely to be a major problem. Ambulances will not always be able to get very near their cases, and also may not be allowed to discharge these in the immediate proximity of a hospital. Therefore, as Dr Bailey has pointed out, some means of doing away with, or at least easing, stretcher-bearing is essential. In this large area of scattered small villages we are trying to solve the problem by having small carriers made by local handymen, each for one stretcher, that can be moved by one person. These are made from old cycle wheels and front forks braced together and fixed at the top to the outside of a wooden frame on which a stretcher can be placed. The weight of a patient keeps this fairly well in position, but four projecting pieces of wood at the corners improve the stability. A leg is also necessary to allow of the carrier being rested. One on a hinge was first tried, but as this was found difficult to work by one person while also supporting the stretcher, a fixed leg has now been found better, even though it has to be somewhat short and does not give a quite level position on standing These carriers are very rough and inexpensive, but will, I believe, do the job for which they are designed. A cycle manufacturing firm has been approached and is considering the possibility of making carriers somewhat on the above lines

R.A.M.C. Training: Some Hints

H. D. McC. writes: May I make a few suggestions which may be helpful to medical men, especially the older ones, who may be called up and go to No. 1 Depot R.A.M.C. for training: (1) Be vaccinated and have your T.A.B. inoculation at your leisure before you go. (2) A bicycle is very useful as the Mess is 1¼ miles from the camp. (3) Break in a pair of boots. (4) A pillow is a great comfort, as the Army ones are hard. The adoption of these suggestions will increase the comfort and render the course not only interesting but pleasant.

MEDICINE 100 YEARS AGO

Extracts from a leading article in the *Provincial Medical Journal* of November 5, 1842:

"A case was tried last week at Barnstaple which requires notice, as it involves a point of law materially affecting the interests of the medical profession. Mr. Joce, a respectable general practitioner, residing at Barnstaple, brought an action against a lieutenant in the navy, named Shapland, for medical attendance. The defendant pleaded the statute of limitations with respect to a large portion of the debt; the remainder, £2 19s. 9d., he admitted on the record.

"It is unnecessary for us to notice the opening speech of Mr Joce's counsel, as it referred to matters unconnected with the point to which we are desirous of directing attention. This point is the alleged necessity of proving the seal of the Apothecaries' Company, in cases where an action for debt is brought by a member of the company. On the part of the plaintiff, Mr. Joce, an attempt was made to prove the seal by the evidence of several medical men, who had formerly received licences from Apothecaries' Hall, and who testified to the similarity between the seal attached to Mr. Joce's license and their own. Mr. Praed, the Recorder of Barnstaple, before whom the case was tried, decided that such evidence was insufficient. . . . Mr. Joce's counsel was not prepared to bring forward any evidence of the kind required by the court, and Mr Joce was accordingly non-suited . . .

"The point of law upon which Mr. Joce was defeated is by no means a new one; it has been debated over and over again in courts of justice. It is agreed upon all hands that the certificate must be proved, and the only question which remains is, what is considered sufficient proof in a court of law. The Recorder of Barnstaple seems to think that it is necessary to prove the seal of the court, but herein we believe him to be in error. Several of the judges have decided that it is merely necessary to produce the original certificate granted to the plaintiff, and to give reasonable evidence of its being a genuine document. This may be done by proving the signature of one or more of the persons whose names are attached to the certificate as examiners, and showing that such persons acted as examiners at the time of signing the document."

THE HEALTH OF THE DOCTOR*

BY

A. HOPE GOSSE, M.D., F.R.C.P.

Physician to St. Mary's Hospital and the Brompton Hospital

I chose for this address the subject of mortality and morbidity among medical men because I believe I have had unique experience of this subject, and have access to innumerable records in connexion with it. I shall unfold to you the causes of death, as well as the amount of ill-health and its various causes, among medical men who start with good average health, after medical examination, at the average age of 30 and are followed up until 60 or 65 years old. I shall then deal with the claim that coronary thrombosis is the "doctor's disease." The family history of those who develop coronary thrombosis and pulmonary tuberculosis will be contrasted with that of the healthiest members of the profession who are still in active practice at the age of 65.

It is important to remember that this experience applies to those who enjoy good health at the average age of 30 and have a good prognosis for health and life. As it would have been an insuperable task for me, even if it were worth while, to analyse the records of all the years, 1938 was chosen for a detailed analysis as it was the last pre-war year and there was no epidemic.

In that year there were under observation 8,884 medical men drawn from all branches of the profession, including dental surgeons. Their ages ranged from 25 to 65 in the following age groups: 25 to 35, 2,411 ; 35 to 45, 3,604 ; 45 to 55, 1,799 ; 55 to 65, 1,070. The average age at which the men came under observation was just over 30 years, and they were not followed after 65 years of age. The ill-health of the doctor will be divided into those diseases which cause death, and those which cause disablement from following any part of his professional work for a period of at least 7 days, such disability being certified by a registered medical practitioner. Illness causing inability to work for any period shorter than 7 days was not observed, and is not included in this analysis. The source of my material is such that the investigation can be regarded as based on complete and reliable records. I have been unable to find any comparable figures (for total numbers, accuracy of records, and the number of years followed up) either for the medical or for any other profession or grade of worker.

Mortality Rate

I shall now deal with the mortality of doctors during their most strenuous working years from the ages of 25 to 65, based on the deaths in 1938 among the 8,884. Deaths occurred in all decades and in the following numbers:

Ages	Nos Observed	Deaths	% Deaths
25–35	2,411	8	0 33
35–45	3,604	9	0 24
45–55	1,799	8	0 44
55–65	1,070	16	1 5

In 1938, however, the death rate of ages 25 to 35 was noted to be high, with 8 deaths, so the same decade for 1939 was analysed. It showed only 3 deaths out of approximately the same numbers of doctors, a percentage of 0.12—a fairer figure for the annual experience of that decade. With this corrected figure it will be noted that the annual death rate increases in each decade, as we would expect, but in the following ratio—0.12:0.24:0.44:1.5, or as 1:2:4:13. As, however, each man is exposed to the annual death rate for his decade for 10 years before he passes into the next decade his risk for each *decade* must be 10 times the annual risk, and these figures amount to 25 ; in other words, 1 in 4 doctors die before the age of 65, or it may be more happily stated that 3 out of 4 doctors survive till 65 years of age.

It is true that 41 deaths a year among 8,884 men for 40 years gives a death rate of only 18.4% ; but this method of calculating does not take into account that the average age of the 8,884 in 1938 was 41½ years. This average age of 41½ is lower by 3½ years than the mean between 25 and 65 years of age, and the lower years have been shown to have a lower mortality.

What are the causes of early death among doctors? In addition to the year 1938, when there were 41 deaths, I took the year 1939 and up to May, 1940, so as to get 100 consecutive deaths among these 8,884 doctors, omitting those from enemy action. The causes of 89 deaths were obtained ; the causes of 11 could not be determined, so I took the next 11 deaths to get a consecutive 100 in which death certificates were available.

Causes of 100 *Consecutive Certified Deaths in* 8,884 *Doctors*		*J Amer. med. Ass.* 100 *Consecutive Death Notices at all Ages*

Causes of Illness among Doctors

What are the causes of morbidity among doctors? Let me first repeat that no account is taken of illnesses of less than 7 days, but all illnesses in which the doctor was unable to do his work for 7 days or over are included. In the year 1938, 1,620 of the 8,884 doctors were ill for over a week, in many instances for many weeks. Some of them had been ill for months or years; on the other hand, some were only beginning long illnesses. These 1,620 were certified by registered medical practitioners as suffering from the following disabilities:

These 1,620 doctors were totally incapacitated for 7,040 weeks in the first six months of their illness and 3,942 weeks in the second six months, a total of 10,982 weeks. In other words, 1,620 doctors out of 8,884 were ill and unfit for work for 10,982 weeks in 1938, an average illness rate of 47 days each, while 7,264 doctors did not have a week's illness; the average sickness for the 8,884 was therefore 8.6 days a year. To generalize, every doctor must expect to have an average of 8.6 days of illness every year from the age of 25 to 65.

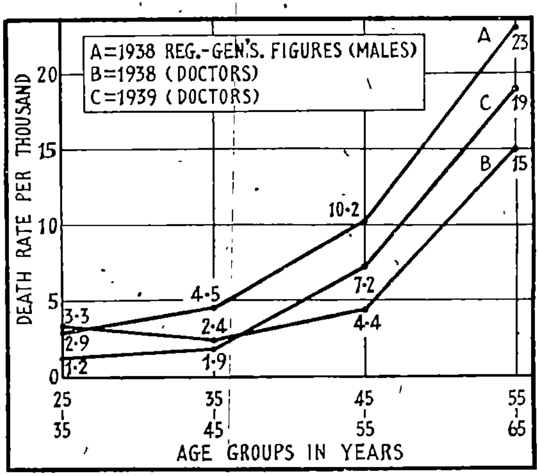
As a check on these figures and the conclusions drawn I investigated the amount of sickness in 100 consecutive doctors who reached the age of 65. They had been under observation for an average of 30½ years, and had suffered 3,314 weeks' illness—that is, an average of 7.5 days every year from the age of 35 to 65. Those who reach the age of 65 might be acclaimed as slightly tougher than the whole group, which includes those who fall by the wayside and die on the journey, perhaps after a long illness. Seven out of the 100 doctors did not have a week's continuous illness during their working lives.

Coronary Thrombosis

The title of "the doctor's disease" has been given to coronary thrombosis. The reason for this may lie in the last published Decennial Report of the Registrar-General relating to the deaths in England and Wales for 1930, 1931, and 1932. The causes of death were tabulated under 86 groups of occupations, and the report shows that the deaths from angina pectoris or coronary disease among 25,000 physicians and surgeons amounted to 70. This was no less than 368% of the average of all occupations, and was commented on as follows: "Their angina pectoris ratio of 368 was much the highest amongst the 86 occupations, being 64% in excess of the ratio for the remaining occupations in Social Class I and 11½ times as great as that for agricultural labourers."

It must be assumed that deaths from coronary thrombosis were then usually certified as angina pectoris. It was at that time that a new conception of coronary thrombosis had been demonstrated to us by our colleagues in America, and this new and accepted conception was applied to the deaths of doctors before it permeated the certificates of all other social classes. It is to be expected that the Registrar-General's next Decennial Supplement will show a further increase for doctors and a far greater increase in all other classes of workers as this cause of death is substituted for myocardial degeneration. The Registrar-General on page 57 referred to "the still more rapid increase in certification of deaths due to angina pectoris." A fairer comparison may be to take the total of deaths due to "heart diseases," which shows that physicians and surgeons had a mortality 138% of the average of the community. This figure is still high, but it does not bear the enormous significance of over three and a half times the death rate from angina pectoris of the general population. The Registrar-General seems to have taken the same view, for on page 60 the following much-less-quoted statement is found: "It would appear that degenerative disease in the heart affects all classes of males to much the same extent, but whereas amongst men whose social conditions are most favourable it tends to express itself in forms diagnosed as angina pectoris or coronary disease, at the other end of the scale it tends to take forms described on death certificates as myocardial degeneration."

In the *Proceedings of the Staff Meetings of the Mayo Clinic* for Nov. 5, 1941, p. 714, is an article by F. A. Willius entitled "A Talk on Cardiac Disease among Physicians." He opens his paper thus: "Why do so many physicians die from heart disease?" and goes on, "The cardiac death rate among physicians to-day is appalling. Anyone doubting the authenticity of this statement need only peruse the obituary list of any current number of the *Journal of the American Medical Association* to find death ascribed to heart disease in 30 to 60% of cases in which the cause of death is stated. In the majority of instances coronary disease is the cause of death, and coronary thrombosis is the ranking killer." A fallacy is avoided by the words "in which the cause of death is stated." It is quite possible that when only 42 out of 100 death notices mention the cause of death these may include all the coronary thrombosis deaths. It would appear from my list that 27 out of 100 deaths among doctors before the age of 65 are due to cardiovascular degenerative causes and 9 to cerebral vascular degenerative causes. Even then their death rate is lower than for the male population of England for the same year.



Where is the evidence that any other profession or trade has a lower rate than 27 cardiovascular deaths in 100 deaths before age 65? I cannot find it. I do not think it exists. I do not believe coronary thrombosis is "the doctor's disease." The true position in Great Britain is that 1 doctor in 4 dies before he reaches the age of 65, and 1/10 of 1 in 4, or 1 in 40, dies from coronary thrombosis, and less than 1 in 10 up to 65 years of age dies from all cardiovascular and cerebrovascular degenerations, including coronary thrombosis.

It then appeared to me of interest to analyse the family histories, as known at the age at which a man comes under observation, in those who suffered from coronary thrombosis or pulmonary tuberculosis, and as a control those who reached the age of 65 and were in work at that age. They are set out in the accompanying table.

Family Histories

	Of 37 who died of or developed Coronary Thrombosis	Control Group of 37 at Work at 65	Of 37 who suffered from Pulmonary Tuberculosis
Parent died of vascular hemiplegia	6	7	3
,, ,, ,, heart disease .	5	5	5
,, ,, ,, angina	2	1	1
,, ,, ,, pulm. tuberculosis	1	0	1
Brother or sister ,, ,, ,, ,, ..	4	3	3
Relative ,, ,, ,, ,, ..	2	0	0
Mean blood pressures: Systolic ..	133	130	130
Diastolic ..	80	86	81
Average weight	12 st. 12 lb	11 st. 5 lb.	11 st. 10 lb.

From these small figures it might be misleading to be at all dogmatic; but in general it may be said that there is no evidence at all here that men who develop coronary thrombosis have had a parentage with a bad family history of early cardiovascular disease. The healthiest doctors at the age of 65 have had a similar family history of cardiovascular disease, and much the same may be said of those who develop pulmonary tuberculosis; my inference is that the same experience would be found in the same number of doctors suffering from other diseases. Also, it can be generally stated that the medical men who develop pulmonary tuberculosis between the ages of 30 and 65 have no worse tuberculous family history than the healthiest doctors, nor indeed than those who develop coronary thrombosis. I believe the converse is true: that a family history of tuberculosis is negligible after the age of 30, and even before that age.

Onset of Coronary Thrombosis.—The records were then searched to find at what ages coronary thrombosis occurred, how many died of this illness, how many survived and were unfit to work again, and how long those worked who completed their convalescence.

Ages at Onset			Deaths	Unfit for Work	Returned to Work
35–45	45–55	55–65			
7	19	11	11	8 years, 1 5 ,, 3 4 ,, 1 1 ,, 3	18* Working : 4 years, 2 3 ,, 6 2 ,, 2 1 ,, 4 <1 ,, 2 Reached 65 2
Approx. No. of Living in Each Group in 100s :					
36	18	11			

* Average duration of unfitness for any work was 18 weeks.

From this it can be said that out of 37 who develop coronary thrombosis 11, or approximately 1/3, die, 8 become ambulatory but unfit for work, whereas 18, or half of them, are working after a year or for a few years. Liability to coronary thrombosis steadily rises with successive years, as one would expect, but only to the age of 45, when a plateau is reached which remains flat to the age of 65.

Onset of Tuberculosis.—At what ages do the 37 who suffered from tuberculosis develop their disease?

Ages at Onset				Deaths	Unfit for Work	Returned to Work
25–35	35–45	45–55	55–65			
16	12	8	1	6	10 (up to 9 years)	21* Working : 23 years, 1 12 ,, 1 7 ,, 1 5 ,, 3 4 ,, 5 3 ,, 5 2 ,, 2 <2 ,, 3
Approx. No. of Living in Each Group in 100s :						
14	36	19	11			

* Average duration of unfitness for any work was 65 weeks.

Summary

1. The causes of death among doctors before the age of 65 have been stated.

2. The causes and incidence of ill-health among doctors have been tabulated.

3. The title of "the doctor's disease," given to coronary disease, is challenged.

4. It was found that the parental history as regards cardiovascular degeneration was the same for 37 doctors who developed coronary thrombosis as for a control group of 37 doctors who were still working at the age of 65, both these groups having been passed fit at the age of 30.

5. It was also found that the parental history as regards pulmonary tuberculosis was the same for 37 doctors who developed pulmonary tuberculosis as for the control group of 37 doctors who were still working at the age of 65, both these groups having been passed fit at the age of 30.

During the Balkan campaign according to German experience (Weller: *Dtsch. Militärztz.*, 1941, 11) the principal diseases occurring were dysentery and influenza. Acute influenza was often difficult to distinguish from typhoid. The percentage of cases of bronchopneumonia (41) was high. Half of the cases were treated with sulphonamides and the other half with "novalgin" and quinine. The results were the same in both groups. The author believes that the best results were obtained by intravenous injection of quinine-calcium.

THE CLINICAL SIGNIFICANCE OF THE Rh FACTOR

BY

K. E. BOORMAN B. E. DODD, B.Sc.

AND

P. L. MOLLISON, M.B., M.R.C.P.

(*Concluded from p.* 538)

Haemolytic Transfusion Reactions Due to Rh Antibodies

As first pointed out by Wiener and Peters, the repeated transfusion of Rh-positive blood to an Rh-negative individual may be followed by a haemolytic reaction due to the production of Rh antibodies as a response to the first or subsequent transfusions. The following case is probably of the mildest type of this reaction.

A Mild Type of Reaction

Case 1.—A man aged 25 had had symptoms of ulcerative colitis for 8 years. In November, 1940, he had a relapse and received two transfusions totalling 2,500 c.cm. of citrated stored blood of group O. These transfusions were followed by clinical improvement, and the patient remained well for many months. He was readmitted to hospital in April, 1942, with a return of symptoms, however, and in view of the success of the previous treatment it was decided to give him a further transfusion. He was found to belong to group O Rh-negative. His serum was tested against a series of group O bloods and found to give no reactions at all at 37° C. or at any other temperature. It was therefore considered safe to proceed with the transfusion of blood from two of these donors. For purposes of record these bloods were also tested with anti-Rh sera and found to be Rh-positive.

1,000 c.cm. of citrated blood from these two donors was given slowly over a period of 5 hours. Following the transfusion the patient had a slight headache and a rise of temperature to 100° F. but no other symptoms, and when seen on the next day expressed himself as feeling better for the transfusion. A venous sample was obtained 48 hours after the transfusion for comparison with the pre-transfusion sample. It was found that only insignificant changes in haematocrit and haemoglobin values had occurred; at the same time it was noted that the serum of the later sample was distinctly yellow, in contrast with that of the pre-transfusion sample, which was pale. A test was made to see whether the Rh-positive blood was surviving in the recipient's circulation by testing a suspension of blood taken from him with a potent anti-Rh serum. Many moderate-sized clumps were found in the suspension, thus indicating the survival of a substantial part of the transfused blood, since a control test with the recipient's blood before transfusion showed no trace of agglutination.

A further sample was obtained upon the fifth day, and it was noted that the serum was even more icteric; a quantitative van den Bergh test showed that it contained 1.5 mg. per 100 c.cm. Examination of the serum with a series of group O bloods revealed the presence of an Rh antibody. A survival test showed that only a small amount of Rh-positive blood was now present in the circulation. On the seventh day after transfusion there was no trace of the donor blood in the recipient's circulation, and the Rh antibody had risen further in titre.

Throughout the period of observation the patient continued to improve slowly, and he left hospital on the eighth day. Blood urea estimations were carried out upon the fifth and seventh days after transfusion; strictly normal values were found.

Reactions in Recently Delivered Women

The frequency with which intra-group haemolytic transfusion reactions occur in women whose infants are affected with erythroblastosis foetalis has been stressed by Levine, Katzin, and Burnham, and corroborated by Wiener. In the present series of investigations 4 such cases have been encountered. Two illustrative cases are here quoted to demonstrate the variation in severity of the reactions.

Case 2.—A woman aged 25: two previous pregnancies. The first was normal throughout, resulting in the birth of a normal baby. The second resulted in a baby which developed jaundice during the first week of life, but subsequently improved without relevant treatment. After delivery the mother was found to have high blood pressure, oedema, and albuminuria. During the third pregnancy she remained well until about the eighth month, when swelling of the ankles, albuminuria, and hypertension developed. At this time the uterus became suddenly more bulky and hydramnios was diagnosed. On June 9, 1942, she was delivered of twins, the first of whom died after 2 to 3 hours and the second after 8 hours. Both infants had gross ascites and all the other features of hydrops foetalis. On the fifth day after delivery it was decided to give the mother a transfusion because of her anaemia. It was found that the patient's group was O Rh-negative, and that her serum contained an Rh antibody. (The twins were group A Rh-positive.)

Two group O and supposedly Rh-negative donors were selected by tests made with the patient's serum and with another human serum containing only moderately-active Rh antibodies. A concentrated cell suspension was prepared from the blood of these two donors and transfusion was begun at a drip rate By the end of an hour approximately 250 c.cm. had been given without any untoward reaction. Shortly afterwards, however, the patient started to complain of violent lumbar pain, difficulty in breathing, and generalized discomfort. The transfusion was stopped, approximately 300 c.cm. having been given, but she started to shiver and had a violent rigor followed by a rise in temperature. A venous sample was obtained 3 hours after the beginning of the transfusion, and it was found that the serum had become intensely icteric. Examination of the recipient's blood confirmed that her cells were group O Rh-negative, type MN, and that her serum contained an Rh antibody. The blood of both the donors was now retested with a sample of human serum containing very potent Rh antibodies. and it was discovered that one of the donors was Rh-positive (and the other Rh-negative). Both belonged to type N. By means of the differential agglutination technique it was possible to show that by the day after the transfusion the recipient's blood stream contained only half the expected number of type N cells (the calculation being made from the known amount and known red cell count of the blood transfused) Moreover, there was no trace of reaction with the potent Rh antiserum. It thus was clear that the blood of the Rh-positive donor had been eliminated, whereas that of the Rh-negative donor had survived. The fate of the latter cells was investigated by tests made during the following few weeks; it was found that they were only slowly eliminated.

Since the post-transfusion sample contained no free haemoglobin in the serum it was not surprising that the patient's urine was free from this pigment. The subsequent course of the case was entirely favourable.

Case 3.—A woman aged 36: four previous pregnancies. The first was terminated by craniotomy of the foetus because of disproportion. The second child was born prematurely after induction of labour a week or so before term. The child was very jaundiced, and died on the second day. The third pregnancy terminated in the birth of a stillborn child at 8 months. The fourth pregnancy resulted in the birth of a macerated foetus at 7 months. The fifth pregnancy was terminated by Caesarean section on Aug. 26, 1942. A living female child was delivered, but slight jaundice was apparent. At the end of 24 hours it was more jaundiced, and on the 28th a blood count showed R.B.C. 1.89 millions per c.mm., Hb 52%, and normoblasts approximately 16,000 per cmm. The infant died on Aug. 29.

Following the Caesarean section the mother became rather collapsed, and 20 oz. of citrated blood of group O were given. An hour after the end of transfusion she had a rigor, and 6 hours later complained of severe abdominal pain and backache and the respirations rose to 56 a minute. On the day after transfusion she was slightly jaundiced, and 29 oz. of dark brown urine were obtained by catheter. During the next 4 days only 12 oz. of urine altogether were passed. and the patient died suddenly on Aug. 31. Microscopical examination of the kidneys showed the typical features of necrosis of the tubules and the presence of masses of pigment in the tubular spaces.

Investigations carried out on Aug. 30 showed that the patient belonged to group A and was Rh-negative; her serum contained an Rh antibody. Her husband's group was O Rh-positive. A test was made by the "inagglutinable count" technique to see whether any of the group O blood given 4 days previously was surviving. It was found that this blood had been completely eliminated from the recipient's circulation. It was thus clear that the blood had been incompatible, and on examination it was found, as expected, that the donor was group O Rh-positive.

Transfusion of the Affected Infant

Levine, Burnham, Katzin, and Vogel have already reported that after the transfusion of Rh-negative blood the infant maintains higher values of R.B.C. count and Hb concentration than after the transfusion of Rh-positive blood. Nevertheless, from observations of changes in R.B.C. counts and Hb concentration it is difficult to reach decisive conclusions unless considerable and consistent differences are found. A more reliable method of demonstrating the different survival of Rh-negative and Rh-positive blood in the circulation of infants affected with erythroblastosis is to use the method of differential agglutination. By an elaboration of this method it is possible after transfusing a mixture of Rh-negative and Rh-positive bloods to estimate the survival of the two types separately. The result of these experiments will be reported later (Mollison), but the following preliminary conclusions are set out, since they appear to be important from the point of view of treatment.

The rate of destruction of Rh-positive blood in the circulation of affected infants varies enormously from one case to the next. In some cases only slight differences have been found between the survival of Rh-positive and Rh-negative blood More often, however, very great differences have been observed The fact that there is a group in which the period of survival of Rh-positive blood is so much shorter than that of Rh-negative blood makes it very desirable to use Rh-negative donors as a routine for transfusion in cases of erythroblastosis foetalis.

Discussion

Iso-immunization in Pregnancy

Dienst (1905) first noted that when the mother's serum contained an agglutinin that was incompatible with the infant's erythrocytes the potency of her iso-agglutinins increased considerably during the fourth to eighth days after delivery. Jonsson (1936) made a study of the sera of women 2 to 3 months after delivery and found evidence of specific stimulation in some cases of "hetero-specific pregnancy": that is to say, when the mother belonged to group O and the infant to group A, for example, the mother's anti-A agglutinins were found to be stimulated. Jonsson did not titrate the sera, but simply used the presence of iso-haemolysins as evidence of an immune response. For this reason probably, he found evidence of specific stimulation in only a certain proportion of cases As mentioned above, Levine and Stetson first suggested that the presence of atypical agglutinins in the serum of a recently delivered woman might be the result of immunization to an antigen in the foetus; and Levine *et al.* soon afterwards described many cases in which the atypical agglutinin had been found to be anti-Rh, and thus developed their theory of the aetiology of erythroblastosis foetalis, as outlined above. Naturally some explanation is needed for the fact that the presence of immune anti-A agglutinins in the serum of a mother carrying a baby of group A usually leads to no obvious abnormality in the baby, whereas the presence of immune anti-Rh agglutinins is so often associated with erythroblastosis of the (Rh-positive) infant. Wiener has suggested that this is because the Rh factor is found only in the erythrocytes, whereas the A and B substances are present in all the body tissues and secretions (in the majority of individuals whose erythrocytes contain the A or B factor), and thus protect the erythrocytes from damage. Levine *et al.* have suggested that in those individuals of group A, B, or AB whose body fluids do not contain the group-specific substances (the non-secretors of Schiff) the presence of immune anti-A or anti-B agglutinins in the mother's serum may lead to erythroblastosis. It may be pointed out that in any case in which the immunizing factor, be it Rh or A or B, is present only in erythrocytes, it is necessary to postulate the actual entry of foetal erythrocytes into the maternal circulation for immunization to occur.

Wiener (1942) has suggested that other atypical agglutinins besides anti-Rh may occasionally be the cause of erythroblastosis. The presence of atypical agglutinins, different from anti-Rh, in the serum of a recently delivered woman has been reported by Levine and Polayes (1941), among others.

In the series of cases described here, in which the infant had definite erythroblastosis, an immune agglutinin incompatible with the infant's erythrocytes was found in the mother's serum in every case In 44 out of 48 cases this agglutinin was anti-Rh, although in some of them immune anti-A or anti-B agglutinins were also found. In the remaining 4 only immune anti-A or anti-B agglutinins were observed. Moreover, in these 4 the presence of other atypical agglutinins was unlikely, because the mother's serum did not agglutinate any of a series of 10 to 20 group O bloods when tested at different temperatures. This observation supports the idea that anti-A or anti-B agglutinins may occasionally cause the destruction of foetal erythrocytes of group A or B and thus be the chief aetiological factor in some cases of erythroblastosis foetalis.

The failure to demonstrate Rh agglutinins in the infant's serum in the majority of cases is not surprising, since these antibodies are not usually present in high titre in the mother's serum and since they will be expected to be absorbed on to the infant's (Rh-positive) cells. Nevertheless, as we have said, they could be readily demonstrated in one case in which the sera of identical twins who lived for only a few hours after birth were examined post mortem.

It will be noted that in the present series Rh antibodies have been found far more often than in the series described by Levine and his co-workers. The technique used by the latter authors consisted in incubation of the mixture of cells and serum (30 to 60 minutes at 37° C.), followed by centrifugation at low speed (500 r.p.m.) for one minute and by gentle shaking to resuspend the sediment. The tubes were then examined macroscopically for evidence of agglutination, and apparent negatives were examined microscopically. We have found that this technique is not so sensitive as that of simply allowing the mixtures to stand in the incubator for 2 hours, followed by examination of the pattern of the sediment and by a withdrawal of a portion of the sediment for microscopical examination, the latter operation being carried out with delicacy. Even the gentle shaking of the tubes advised by Levine *et al.* may, in our experience, completely abolish a weak reaction. It is of course necessary to carry out control tests with Rh-negative cells if weak reactions are to be accepted as evidence of the presence of an Rh antibody.

Selection of Blood Donors for those who have become Immunized to the Rh Factor

In the 3 cases described in which haemolytic reactions followed the transfusion of Rh-positive blood to an Rh-negative individual who had previously been immunized to the Rh factor, it will be noted that the essential feature is a rapid elimination of the donor blood from the recipient's circulation. This finding is in striking contrast to the survival time of compatible blood, which has been shown to be consistently 80 to 120 days (Wiener, 1934; Mollison and Young, 1942). From the 3 cases quoted above the impression may be gained that serious sequelae are the exception and not the rule following the transfusion of Rh-positive blood to a person whose serum contains an Rh antibody. However, it should be mentioned that in the 2 cases of which details have not been quoted the transfusion was followed by oliguria with a steadily rising blood urea. In these cases the patient, after being critically ill, at the end of 7 to 10 days after transfusion gradually started passing normal quantities of urine again, and recovered. Even in Case 1, in which there were apparently no untoward consequences at all, it is clear that the transfusion was of no benefit to the patient.

In Case 2 it was demonstrated that Rh-negative blood survived normally in the recipient's circulation after transfusion, and Wiener (1941) has published many such cases in which he has been able to demonstrate that Rh-negative blood survives normally.

For the transfusion of any recently delivered woman, and particularly in any case in which there is a suspicion that the individual has become immunized to the Rh factor, it is clearly very desirable to have available a panel of Rh-negative donors. At present large stocks of potent Rh test sera are not available, but if the recipient's serum is found to be incompatible with the donor's cells it should be possible to test the serum against a number of other individuals and to find a compatible donor.

It is probable that a modified compatibility test, as described above, will serve to detect the majority of cases in which Rh agglutinins are present. Clearly it will be of further help to know whether the prospective recipient is Rh-negative or not. It is strongly recommended that this modified compatibility test be used as a routine before the transfusion of recently delivered women is undertaken. Where there are no facilities for carrying out this test two compromise procedures are available:

(*a*) In any case in which there is reason to suspect that the infant has erythroblastosis, or if there is a suspicion that any previous infant has had erythroblastosis, transfusion of the mother should be avoided if possible. Obstetric shock, post-partum haemorrhage, etc., should be treated by serum or plasma transfusion. Cases in which erythroblastosis is suspected should include all cases in which the infant is stillborn without obvious cause, and all cases in which the infant is born with oedema, jaundice, or obvious anaemia. (*b*) Rh-negative donors should be used as a routine either for the group mentioned in procedure *a* above or, better still, for the transfusion of all recently delivered women. This latter procedure has already been adopted by Levine *et al.* (1941) and Wiener (1941), but it must be pointed out that its immediate application on a large scale would present very great difficulties.

In discussing the choice of a donor for the affected infant the question of the suitability of the mother or father naturally arises, since they may be the only donors readily available. In this, as in all transfusions, the most important factor is the compatibility of the donor's erythrocytes with the recipient's serum. Compatibility in this case, however, has to be defined as "enjoying normal survival in the recipient's circulation," because it is not usually possible to demonstrate Rh agglutinins in the infant's serum, even in cases in which rapid elimination of Rh-positive blood is observed. From the point of view of the donor's erythrocytes the mother is suitable and the father unsuitable.

There is another factor to take into account, however—the compatibility of the donor's serum with the recipient's erythrocytes. This factor is ignored by some clinicians who regularly use, for instance, individuals of group O for transfusion to individuals of any group. Nevertheless, as demonstrated recently by Aubert, Boorman, Dodd, and Loutit (1942), the transfusion of serum containing potent incompatible agglutinins can result in the destruction of some of the recipient's erythrocytes. In infants who have developed a haemolytic anaemia as the result of the passage of Rh agglutinins through the placenta it is obviously undesirable to transfuse further amounts, and for this reason the transfusion of blood from the mother is to be deprecated.

Clearly, the ideal donor is an Rh-negative individual whose serum does not contain an Rh antibody and whose blood is also of the same group as the infant. However, when the infant is of group A and the mother is group O Rh-positive, and the destruction of the infant's erythrocytes is due to the mother's anti-A agglutinin, as we have supposed above, the most suitable blood for transfusion will be group O the serum of which contains low-titre agglutinins, since, by analogy, group A blood will probably be destroyed more quickly than group O blood in the infant's circulation.

To sum up, the most suitable donors for the majority of erythroblastotic infants requiring transfusion are group O Rh-negative persons whose serum contains only low-titre agglutinins. Since they will also be the most suitable donors for transfusion for the majority of recently delivered women, it seems very desirable for every donor organization to collect a group of such individuals.

Incidence of Affected Infants in Different Families

When a case of erythroblastosis has occurred in a family some help may be given in the prognosis regarding future children by testing the blood of father, mother, and any available siblings. If, for instance, the mother is Rh-negative and the father Rh-positive and any of the children are Rh-negative, it is clear that the father's genotype is Rhrh, and therefore there is an even chance that future children will be Rh-negative and presumably not affected with erythroblastosis. If, on the other hand, all the children are Rh-positive, it will be more likely that future children will be affected.

Summary and Conclusions

In every case of erythroblastosis examined the serum of the mother has been found to contain an immune agglutinin which is incompatible with the infant's erythrocytes. In 44 out of 48 cases the agglutinin was anti-Rh. In the remaining 4 cases it was either anti-A or anti-B. Because of this latter finding it is considered that the anti-A and the anti-B agglutinins are capable of causing destruction of the infant's erythrocytes in a certain number of cases and thus, in some instances, of being the main causative factor of the erythroblastosis. The finding of weak Rh antibodies in the sera of the mothers of some babies with "physiological jaundice" supports the idea that there is no clear-cut distinction, from the clinical point of view, between mild and severe jaundice of the newborn.

At the present time, if serological tests are used as an aid in the diagnosis of doubtful cases of erythroblastosis, compatibility of the mother's serum with the infant's erythrocytes may be regarded as a strong point against the diagnosis, provided that the mother's serum is examined by a sensitive technique between 7 and 21 days after delivery. On the other hand, if the mother's erythrocytes are shown to be Rh-negative and her serum is found to contain anti-Rh agglutinins, the diagnosis is strongly supported.

A change in the method of selection of blood donors in certain cases is urgently needed. This applies particularly in the case of transfusion of recently delivered women and, above all, whenever there is any suspicion that the present infant is affected with erythroblastosis or when there is any previous history of the birth of jaundiced babies or of stillbirths without obvious cause.

At the same time, a modification of the present method of testing for compatibility between the bloods of donor and recipient must be made. Methods for carrying out these tests are described, and compromise procedures are discussed for cases in which there are no facilities for making these tests.

It is recommended that every blood bank takes steps to establish a panel of group O Rh-negative donors whose blood will be available, first, for the transfusion of the cases referred to above, and, secondly, for use as a routine in the transfusion of infants affected with erythroblastosis (when transfusion is required).

We should like to thank the staff of the Hospital for Sick Children, Great Ormond Street, and the following medical officers, all of whom have given us much help by drawing our attention to cases and allowing us access to them, and in many instances by collecting samples and supplying very useful clinical information: Drs. J. F. Ackroyd, M. Bannister, A. B. Bentall, R. K. Bowes, D. Daley, P. Dingle, A. B. Field, V. B. Green-Armytage, L. G. Higgins, Evan Jones, H. M. M. Mackay, H Levy, R. G. Macfarlane, J. Murray, J. V. O'Sullivan, E. B. Petrie, M. M. Pickles, R. B. K. Rickford, R. C. Thomas, R. B. Tulk-Hart, Janet Vaughan, and Prof. Young. We should also like to thank Dr J. F. Loutit for help and facilities in carrying out this work

The Queen has expressed her great interest in a plan launched by the Central Council for the Care of Cripples to open a new residential home and school for severely crippled boys, and has sent a donation of £1,000 which had been placed at her disposal by members of the "Bundles for Britain" branches in America to be used for the children of this country. The council has been deeply impressed with the great need for more homes in the reception areas for severely crippled children, who cannot easily move about and whose parents are often unable, under war conditions, to care for them adequately. The Shaftesbury Society, one of the council's affiliated members, which has had wide experience in running homes, has agreed to open this new home provided the necessary capital of £10,000 can be raised. About half the sum has now been promised.

OPTIMAL PROPORTIONS OF ANTIGEN AND ANTIBODY IN TESTS FOR Rh ANTIBODIES

BY

(From the Galton Laboratory, Department of Pathology, Cambridge)

That the extent of the reaction resulting from mixing homologous antigen and antibody in a test-tube depends very largely on the proportions of the two reagents in the mixture has long been known. The proportions optimal for reaction can be determined (Dean and Webb, 1926, Duncan, 1932), but, while a particular antigen and its antibody will in suitable proportions produce a very well marked reaction, it may be possible, by varying the relative amounts of the same reagents, to get a mixture in which no reaction can be seen. Goldsworthy (1928) found that a specific antibody in the serum of a patient suffering from hydatid cyst of the lung could easily be missed unless the serum and the antigenic fluid, obtained from echinococcal cysts in the livers of cattle, were mixed in proportions suitable for producing flocculation. Workers with precipitins and bacterial agglutinins are familiar with zone phenomena due to the varying proportions of antigen and antibody in the different mixtures of titrations. Some human sera containing iso-agglutinins of the A–B–O system of blood groups show zoning: in titration with homologous red cells the best reaction does not take place in the mixture in which the iso-agglutinin is strongest, but in one in which it is more dilute, so that in a titration there is a pro-zone of one or more tubes in the series before those in which reactions are greatest. Although on very rare occasions a serum may be encountered which will show no agglutination with appropriate cells unless it is suitably diluted, zone phenomena give little trouble in testing for the A–B–O groups

We have recently examined a sample of human serum containing antibodies for the Rh blood-group factor of Landsteiner and Wiener (1941). Used undiluted, this serum agglutinated the red cells of strongly positive reactors to anti-Rh, but failed to agglutinate cells from more weakly positive reactors. When, however, the serum was suitably diluted, definite and clear-cut agglutination was obtained with these weaker cells. Landsteiner and Wiener found marked differences in intensity in the reactions given by the red cells of different Rh-positive persons Wiener (1942) mentions that with some human anti-Rh sera, used undiluted, reactions were inhibited until the sera had been heated at 56° C. for 10 to 20 minutes; the behaviour of the serum we describe was unaffected by heating. We obtained the serum in the middle of July, 1942, from a mother (B.)—of group O—who on Nov. 6, 1941, gave birth to a female child (her second), which died of erythroblastic anaemia on Nov. 16, 1941. B. is Rh-negative; a daughter born 2½ years ago is group O Rh-positive.

The Rh Factor

Red cells containing Rh react with immune sera prepared by injecting rabbits or guinea-pigs with the blood of rhesus monkeys. The factor is inherited as a simple Mendelian dominant and is present in about 85% of American whites Boorman, Dodd, and Mollison (1942) have found a similar distribution in England. The examination of a small series of negro bloods suggested there might be racial differences in distribution, and very recently Landsteiner, Wiener, and Matson (1942) found only one Rh-negative person among 120 full-blooded American Indians, whilst among 155 Indians of mixed ancestry the distribution of the Rh factor was intermediate between that for whites and pure Indians, according to expectation. Antibodies for Rh do not normally occur in human plasma, but when Rh blood is given to some of the persons lacking the antigen the body recognizes it as foreign and eliminates it. At a first transfusion the haemolysis may be so gradual as to be unsuspected, but Rh antibodies may then be produced, and Rh-positive blood given at a later transfusion may cause the most serious reactions. Immune antibodies to Rh may be responsible for reactions in women, transfused for the first time, who have recently given birth to a child or had a miscarriage or stillbirth, the antibodies having been formed in response to Rh antigen present in the foetus and inherited from the father but absent in the mother. Such antibodies produced in a mother against an antigen present in her foetus but lacking in herself may be passed through the placenta and may react with and damage the red cells of the foetus, and it seems certain that erythroblastosis foetalis, a familial haemolytic disease of the newborn, is caused in this way and that the antigen most commonly involved is Rh. As most donors are Rh-positive it is of the greatest importance that anti-Rh in the serum of any recipient shall be detected. Human sera containing anti-Rh in sufficient strength are probably the most convenient reagents for detecting Rh.

Technique

The serum of B. was tested, by a technique similar to that used by Landsteiner and Wiener, against the red cells of a panel of known positive and negative Rh reactors of group O. Equal volumes—about 0.05 c.cm.—of the undiluted serum and of red cell suspension consisting of 4 to 5% of whole blood, as judged by eye, were mixed in 2 in. by 1/4 in. precipitin tubes, on which glass caps were placed to prevent evaporation during storage. The tests were made in duplicate, and one set was stored for 2 hours and read at room temperature, while the other was stored in a room at about 37° C. and read there after the same time. The reactions were read by disturbing the sedimented cells in the tubes as gently as possible, and looking for macroscopic agglutination by holding the tube to the light. Some of the contents of any tube that did not show agglutinates visible to the naked eye were transferred to a microscope slide and spread by means of the stem of a Pasteur pipette, using only just enough pressure to ensure that the cell suspension was plainly visible under a low power of the microscope.

The sediment in the tubes was examined, before it was disturbed, by inspecting the base of the tube. Landsteiner and Wiener stated: "Negatively reacting bloods then show a circular deposit with a smooth edge, while positive bloods have a wrinkled sediment with a serrated border or show a granular deposit. From these readings, as a rule, the diagnosis can readily be made." We are sure that what Landsteiner and Wiener say about reading the sediments is quite correct, but we are not yet expert enough to rely as much on this type of reading as on seeing agglutinates themselves either by the naked eye or under the microscope.

Titration Tests

When it was found that the undiluted serum failed to react with some cells known to be Rh-positive these anomalous cells were examined by a titration method. Series of falling dilutions —undiluted, 1 in 2, 1 in 4, etc.—of the serum in equal volumes of normal saline solution were prepared, and equal volumes of cell suspension were added to each tube of a series. When the titrations were read it was seen that the serum produced a well-marked zone, with the earlier tubes showing little or no reaction, but with quite definite reactions in later tubes of the series.

In the Table are shown the results of the titrations with the red cells of four group O Rh-positive persons. There are marked differences in intensity in the reactions given by these persons, and without titration Nos. 3 and 4 would have been aken as negative. Of 14 lots of group O Rh-positive cells in an experiment of which the four examples in the Table are part, five were like Nos. 3 and 4 and would have been diagnosed as negative; they all showed clear-cut reactions in the later tubes of the titration. Duplicate titrations were stored and read at room temperature (21.9° C.): the reactions were much less marked, and No. 4 of the Table and another set, positive at 37° C., gave no reaction even on titration. Levine and Katzin (1940) found a human serum containing anti-Rh which had a greater degree of activity at 37° C. than at lower temperatures, and Mollison and Taylor (1942) have reported that the human anti-Rh sera they have examined react better at 37° C. than at room temperature.

As Landsteiner and Wiener indicated, the reactions given by some sera and some Rh-positive cells are very uncertain, and the intensity of the reactions between the same reagents varies somewhat on different occasions. Sometimes B.'s serum, undiluted, has given a slight reaction, "w," with some of the cells with which on other occasions it reacted only when diluted.

Table showing Titration of B.'s Serum with Cells of Different Rh-positive Persons (Tests Stored for 2 Hours and Read in Room at approximately 37° C.)

Tube No.	Serum Dilution	Cells			
		I	II	III	IV
1	1/1	V	w	—	—
2	1/2	V	++	w	—
3	1/4	C	V	(+)	(+)
4	1/8	C	V	+	w
5	1/16	C	V	++	++
6	1/32	V	V	w	w
7	1/64	++	V	w	w
8	1/128	V	+	(+)	—
9	1/256	w	—	—	—
10	1/512	w	—	—	—

Order of strength of reaction: C>V>++>+>(+)>w

No reaction is scored as negative without a microscopical examination; reactions weaker than V were determined with a microscope.

C=Clumps of cells in clear surrounding fluid visible to naked eye.
V=Somewhat weaker reaction, with clumps distinctly visible to naked eye, although surrounding fluid is not clear.
++=Very big clumps under microscope, + = not quite such big clumps, (+) = less than +.
w=Definite weak reaction in which there is a uniform distribution of very small clumps of about 6 to 8 cells.

Identification of the Antibody in B.'s Serum

The Rh groups of the panel of donors mentioned above had been determined with sera which had been shown to contain Rh antibodies by comparing their behaviour with that of an anti-Rh serum very kindly sent to the Medical Research Council by the Rockefeller Foundation of New York. All of a panel of 18 group O donors—15 Rh-positive, 3 Rh-negative —have been correctly diagnosed by B.'s serum. Paterson, Race, and Taylor (1942) stated that "when the reactions given by a known and an unknown antibody and the same panel of red cells are identical the odds in favour of the two antibodies being the same can easily be calculated. The probability that the apparent identity of the two antibodies is due entirely to chance is given by the formula $\frac{a!\,b!}{n!}$, where n is the number in the panel and a and b the numbers of positive and negative reactors." Applying the present figures, we get $\frac{15!\,3!}{18!}$,* or $\frac{1}{816}$, as the probability that the identity of the results is due merely to chance; in other words, the odds in favour of the antibody in B.'s serum being anti-Rh are 815 to 1. Members of groups other than O have also been properly diagnosed for Rh by B.'s serum, suitably absorbed to remove anti-A and anti-B.

Titration Advisable

Since discovering the necessity for titrating B.'s serum we have, when testing for the presence of Rh antibodies, never been satisfied they were absent until examination by the titration method—6 or 7 tubes—had been made. If B. had needed a transfusion a direct test between her serum and the cells of, say, No. 3 or 4 in the Table would not, without titration, have disclosed the incompatibility. It appears advisable to use a titration method in direct tests between the serum of a recipient and the cells of potential donors if the Rh factor may be involved; and it may be that in some cases titration will prove to be the only method of disclosing incompatibility due to other blood-group factors.

---

* $3! =$ "factorial three" $= 3\times2\times1 = 6$.

Summary and Conclusions

The anti-Rh-containing serum of the mother of a baby which died of erythroblastic anaemia caused, when used undiluted, the agglutination of red blood cells of strongly positive reactors to anti-Rh, but failed, undiluted, to agglutinate more weakly reacting cells. When these weakly reacting cells were added to serial dilutions of the serum well-marked agglutination occurred if the serum was suitably diluted. These findings suggest the advisability of using a titration method before deciding that anti-Rh is not present in a serum, and in direct tests between the serum of a recipient and the red cells of potential blood-transfusion donors.

We are grateful to Dr. T. H. Boon, regional transfusion officer, Newcastle-upon-Tyne, and to Dr S. G. M. Mackay of the Newcastle General Hospital for the trouble they have taken in getting B.'s serum and details of her case.

PHYSICAL TREATMENT OF ACUTE WAR NEUROSES

SOME CLINICAL OBSERVATIONS

BY

WILLIAM SARGANT, M.B., M.R.C.P., D.P.M.

Deputy Clinical Director of an E.M.S. Neurological Unit

During this war there have been few reports on the actual value of the various physical treatments of acute war neuroses. The methods adopted have had not only to be tested in the last three years but also modified from those employed in peacetime. As things have turned out, they have proved a very valuable part of any comprehensive clinical scheme of treatment and rehabilitation for such patients. The scope of psychotherapy and environmental adjustment for acutely ill patients is somewhat limited: there is little time to-day for intensive psychotherapy, and with the country now organized for total war and subject to random bombing it is not always possible to find an environment where the individual is not exposed to stress and can also be usefully employed in the war effort. The aim of physical treatment is to bolster up the constitution so that unavoidable stresses are better tolerated by the individual. Should active fighting on a second front develop or a renewal of severe air raids occur, the sphere of usefulness of such treatments will be greatly enhanced, and a knowledge of their possibilities is consequently of importance to everybody.

In this unit we have had unparalleled opportunities of testing and developing such methods. After the Flanders retreat we admitted convoys direct from the Dunkirk beaches. Subsequently, months or weeks later, during which time their condition had often gravely deteriorated, acute cases were admitted from other sources. During the Battle of Britain we received casualties from coastal areas and bombed aerodromes, and during the long winter aerial bombardment of London we had to deal with patients suffering from acute neuroses who had broken down after weeks or months of useful service as members of the Civil Defence Services. On several occasions bombs were dropped either on the hospital or in the grounds, and at these times and throughout the raids we obtained very valuable experience at first hand on how to use these methods with a unit of neurotic patients presenting a wide variety of panic reactions.

Since over 3,000 Service cases alone, both acute and chronic, have had to pass through our limited bed accommodation, there has been a pressing need to seek means of accelerating processes of normal recovery, of preventing aggravation of existing symptoms, and of getting patients well enough to return either to readjusted duties in the Services or to some useful civilian occupation. Our aim has been to avoid, if possible, a recovery that is long-drawn-out.

Our most important finding has been the supreme need for immediate first-aid treatment of the acute neurosis occurring in a good previous personality. This is best done by physical methods. Application of treatment should be considered in terms of hours rather than of days or weeks. In this way conditioned fears can be to a certain extent prevented from becoming ingrained in the personality, and neurotic behaviour patterns that were primarily released under severe stress from recurring whenever the individual is again exposed to the slightest danger. We have also learnt that the response to treatment depends not only on the speed with which treatment is given but also on innate qualities of personality. No treatment will endow a patient with qualities of stamina that he never previously possessed. A fundamental constitutional stability under ordinary stresses has been found of overwhelming importance to a good prognosis. Previous general instability offers a very poor one.

First-aid Treatment

For the acute panic state, the advantages of heavy sedation given at the earliest possible moment have been amply demonstrated. As a rule too little rather than too much is given. At the first sign of impending breakdown in a good previous personality very heavy sedation, immediately applied to produce unconsciousness for some hours, may stop the development of a neurosis requiring treatment in hospital. The individual's natural stamina is thereby allowed some hours to re-establish itself at a time when his will-power and morale are showing signs of initial failure to cope any longer with the stresses encountered, and he is temporarily open to the acquirement of a wide variety of conditioned fears.

In an emergency alcohol can be used as a means of rapid first-aid sedation, but other chemical methods are preferable. Two to four drachms of paraldehyde, for instance, are very useful, because the drug acts so fast. Six to nine grains of sodium amytal may also be given, or 10 to 20 grains of medinal. But these drugs have the disadvantage of not taking effect for from one-quarter to half an hour. During even this short period the seeds of a future conditioned phobia may be implanted. In the hyperacute condition, especially when the patient is disturbing those around him and destroying their morale, the best method of treatment is the production of immediate unconsciousness by intravenous barbiturates. Whether such first-aid measures will have to be followed by further treatment depends to a certain extent on the physical state of the patient. If he has already lost 1 to 3 st. before he starts breaking down, he probably needs further treatment and rehabilitation, and should be sent back to hospital after these initial first-aid measures. Psychological improvement is rarely permanent if the patient's physique has much deteriorated. However, if the stress has been short-lived though very severe, and if the personality is sound, then deep sleep for some hours may be quite sufficient to enable the patient to carry on his work, especially if initial heavy sedation is supplemented for a day or two by milder sedation.

Breakdown can also be prevented by the judicious use of prophylactic sedation. Courage and will-power have physical components and are certainly not directly dependent on the psyche. Both these attributes of the mind readily weaken if the person is fatigued. Loss of weight, loss of sleep, or even a poor quality of sleep may bring latent weaknesses in the power of resistance to the surface in neurotically predisposed individuals. During a period of temporary crisis the individual's final breakdown can often be averted by the judicious use of sedatives given deliberately to extend to the maximum his limited reserves of nervous energy. Battles are won by hanging on even a few hours longer than the enemy. It was interesting to find soldiers who had been able to go through the stress of Dunkirk fortified by brandy obtained during the retreat but who made a hopeless showing when faced with a minimal stress in England. If such prophylactic sedation is used occasionally in a crisis, addiction need not be feared in any except severely psychopathic cases. Methods of treatment that are useful for the many should not be rejected because of the weakness of a few. As well as the need for sedatives, there is often an alternative one for temporary stimulants to tide over a few hours of fatigue and stress. Here benzedrine may be found exceedingly useful, and again, in normal persons, there need be no fear of addiction. There has been no real evidence of addiction in non-psychopathic types, despite the current popular phobia; even the neurotic individual does not crave for prolonged sleeplessness, which this drug produces.

Numerous publications during the war have emphasized the value of intravenous injections of barbiturates as an aid to restoring the memory of events for which there has been a hysterical amnesia or to investigating a patient's illness from a psychopathological angle. In addition, however, these drugs are extremely useful as a means of dealing with other acute hysterical conversion symptoms, such as the sudden loss of use of an arm or a leg, immediately they occur. The drug is injected, anxiety is rapidly relieved, being replaced by a sense of well-being, and the patient is susceptible to suggestion and the restoration of function in the part affected. This treatment should preferably be given by the medical officer at the casualty clearing station as soon as the symptoms occur. If they are taken early there may be no need for the patient's transfer to a neurosis centre, unless other symptoms need attention. If acute hysterical conversion symptoms are left untreated for more than a few hours the abnormal behaviour pattern becomes more ingrained and obvious escape mechanisms grow more fixed by the patient's removal to a safe area.

Continuous Sleep Treatment

If severe anxiety or hysterical symptoms have continued for even a week or longer, other treatment is necessary which cannot be done except in hospital, though not necessarily very far from the scene of fighting or bombing. By this time physical changes will have become more pronounced and conditioned fears will have taken a firmer hold. A much longer period of sleep treatment is necessary to destroy these. Any sedative drug can be used. Paraldehyde can be given, orally or rectally, in doses of 2 to 4 drachms every four hours; alternatives are 3 to 6 gr. of sodium amytal at four-hourly intervals, hyoscine and luminal as advocated by Mira, or mixtures of these drugs combined, if necessary, with 2 c.cm. of somnifaine twice a day. The aims of treatment are to avoid undue toxicity, to procure 20 hours of sleep out of the 24, to adjust the dose so that sleep is neither too light nor too deep and patients are roused to take their meals, and to see that during the 7 to 10 days the treatment is being continued the patient receives 3 to 4 full meals a day and is given enough fluid to restore his physique and avoid the dangerous toxic effects of the drugs. At the end of the treatment sedation is slowly reduced. Other measures, which were useless while the acute anxiety and physical deterioration dominated the picture, may then be effective. It is wise to clear up outstanding hysterical conversion symptoms, if they are present, by intravenous injections of barbiturates and suggestion before the treatment is started.

Modified Insulin Treatment

Another interesting group of patients admitted to a neurosis centre comprises the good previous personalities who break down only gradually over a long period of stress and have kept on fighting against their increasing symptoms. After weeks or months of intense strain they may find that they are starting to have anxiety and hysterical responses to stimuli that previously left them almost unmoved. By this time they will probably have lost from 1 to 3 st. in weight and they show a peculiar mixture of anxiety, hysterical, and reactive depressive symptoms in proportions depending on their constitutional make-up. They can be superficially responsive to encouragement and psychotherapy: psychotherapy may, in fact, seem the treatment of choice because the patients are reasonably co-operative, but they quickly relapse under any fresh strain, despite a superficial improvement. If, for instance, they are rapidly cured in this state of a conversion symptom and returned to duty, they are shortly readmitted, more discouraged than before. They are often dubbed malingerers because of the insidious onset of the condition, but the doctor's suspicions as to the true nature of the illness should be roused by the fact that their past record is good. They generally retain insight into their deterioration and are ashamed of it. They cannot control their increasing somatic responses to fear stimuli, however hard they try. This type of patient was most often seen among good A.F.S. personnel who had done excellent work during three months or so of the London air raids before breaking down, and among those who tried to carry on for some considerable time after return from Dunkirk despite an increasing nervous disability. They resemble descriptions of the good type of patient who broke down on the western front in the last war after months of hard fighting and good morale. They should be distinguished from the individuals suffering from hyperacute anxiety state or the purer forms of endogenous depression, so far as physical treatment is concerned. They are best treated by a modified form of insulin therapy, which should be carried out in a base hospital, free from conditions of acute stress. The technical details of this treatment have been described elsewhere (Sargant and Craske, *Lancet*, 1941, 2, 212). It has been found most useful for fairly rapid restoration of physique and of some degree of working capacity, though the patients are rarely able to return to the full stresses that precipitated their illness. Of the 300 or more patients that we have treated by modified insulin therapy in this unit, these patients and those suffering from mild reactive depression have done best. Often they will gain a stone or more in a few weeks, and the vicious circle of anxiety and loss of weight and increasing incapacity is broken. The fact that they are being given a definite treatment is not without its psychological effect. On recovery these patients should be sent to modified duties or a somewhat less exacting environment, as they remain conditioned to their past experiences and have a horror of being reduced to a similar state again. In some patients the illness has been started initially by a head injury or by blast effects.

Convulsion Therapy

Among the other good personalities that may break down, especially after three years of war, there are many patients who get sent either to neurosis centres or to mental hospitals. Included among them are the over-conscientious non-commissioned officer with many years' service and the valued industrial worker who are particularly prone to break down into a depressive state because of their previous conscientious obsessional personality. Such patients carry on till they are sleepless, retarded, have ideas of guilt, or blame themselves for failing in their excessively high standard of duty or for letting down their comrades or superiors. These patients do not respond well to modified insulin therapy; despite a large intake of food they do not put on weight. Metabolic changes have occurred which are difficult to reverse and are reflected not only in a depressed attitude of mind but also in a general slowness of bodily movement, easy fatigability, and retardation of thought, speech, and even facial expression. Sometimes this distressing condition can be broken up by a long course of continuous sleep treatment lasting up to three weeks, but this will occur in only a relatively small proportion of the patients treated. One may have to wait months, a year, or even longer for spontaneous recovery to occur, even if the patients are immediately discharged from the Army or removed from stress. They are inaccessible to psychotherapy or reassurance. Convulsion therapy, however, should produce a rapid improvement in up to 75% of those patients with a good previous personality and genuine severe depression. Such treatment carries with it a slight risk of fractures, but has not the far from negligible mortality of a long course of continuous narcosis in inexperienced hands. Fractures can now generally be avoided with clinical skill and correct positioning of the limbs and body. If fractures should occur they will rarely cause a period of disability longer than that of the untreated illness. Therefore, if the illness appears likely to be long, this treatment should be considered. The advantages should be weighed against the risks.

Conclusion

It will be seen, therefore, that methods of physical treatment are now available as an aid to shortening the period of total disability in many acute psychiatric conditions. In good previous personalities acute panic states, acute anxiety states, anxiety hysteria, and states of depression now all have their appropriate treatments along such lines. These treatments must, of course, be used in conjunction with other established methods, both psychotherapeutic and environmental, to bring about recovery, restore the individual's self-respect, and diminish liability to further breakdown. Clinical experience greatly enhances their possibilities, just as poor judgment in the selection of cases may rob them of all effectiveness.

NIGHT VISION IN THE ARMY

BY

B. W. RYCROFT, M.D., F.R.C.S., Major, R.A.M.C.
Command Specialist in Ophthalmology

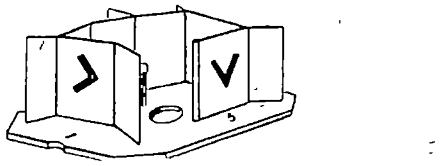
Much has been written on the subject of night vision, which in peacetime has interests of academic value; in wartime, however, the interest must be essentially practical and a contribution to the efficiency of the fighting Services. It follows, therefore, that any investigation of night vision among troops must endeavour to obtain information which will be of value to unit commanders in their conduct of operations.

Briefly such information will consist of: (1) The general state of night vision in the unit as a whole and also in comparison with other similar units. (2) The names of personnel whose night vision is above average and who are especially fitted for night patrols, night leadership, night "spotters," etc. (3) Picked drivers whose night vision is above average and who may safely be trusted to lead a column of vehicles at night in total darkness without lights. (4) Drivers who are night-vision-defective and dangerous in their present military occupations. (5) Contact with the unit as a whole enables an opinion on the general ophthalmic state to be given—e.g., what percentage should be sent for routine examination.

To obtain this information the military specialist in ophthalmology requires portable test apparatus, simple to work and robust in construction, which can be employed throughout the Army to give uniform and standard results. The co-operation of the unit commander is also essential, and, in our experience, is always willingly given in spite of disturbance to training programmes caused by our visits. Thanks to the initiative of the Consulting Ophthalmic Surgeon to the Army, Brigadier Sir Stewart Duke-Elder, the Army now possesses such apparatus, and our experience in 10,000 cases has proved that it fulfils the required criteria stated above.

The Army Night-vision Test

So far as is possible, in any night-vision test, the object is to stimulate the parafoveal and peripheral areas of the fundus. The test object, therefore, in the Army test is a large V mounted in five different positions on a translucent screen behind which is a small bulb run from a dry battery and controlled by a rheostat and voltmeter. The lamp is at varying distances from each of the five screens, which are arranged as an irregular pentagon. The whole apparatus can be rotated so as to bring one screen at a time in front of the patient.



The apparatus. (Drawing supplied by Theodore Hamblin, Ltd.)

Before examination the soldier is asked the following questions: (1) What is your age? (2) Have you any eye trouble and do you wear glasses? (3) How is your sight in the dark? (4) Do you live in the town or in the country? (5) What is your job in civilian life? (6) What is your job in the Army?

The subject sits at one metre from the apparatus and is rendered fully dark-adapted by wearing dark goggles for 30 minutes; at the end of this period these are cleared of moisture—a most essential procedure—and he then writes down the position of the five V's in turn; his night vision is accordingly assessed. If he sees all five V's his night vision is excellent; if he misses all five it is very bad. Thus, night vision 5/5 is excellent; 4/5, 3/5, 2/5, and 1/5 are average; 0/5 is poor.

All that is required for mass examination at the unit location is a dark Nissen hut divided in two by a curtain. On one side the test is conducted; on the other the men wait in their goggles, and clerical work is carried on with shaded lights.

Full dark adaptation is important: after examination the night vision is recorded in the soldier's personal documents, and a record of the entire unit is made, incorporating the previous questions. It is possible to examine 200 men daily with this test, tabulating results as follows:

TABLE I

No.	Rank	Name	Age	Civil Occupation	Army Occupation	Man's own Remarks	Score	T/C	G.
1234	Cpl.	?	29	Clerk	Driver	Fair	3/5	T	—

T/C=Town or country; G= whether or not the man wears glasses

Analysis

When the unit has been examined the results are carefully analysed, and classification into three main groups is made thus:

(A) Men whose night vision is above average—i.e., 5/5
(B) „ „ „ „ „ average—i.e., 4/5, 3/5, 2/5, 1/5
(C) „ „ „ „ „ below average—i.e., 0/5

The night-vision defectives are further analysed to indicate to the unit commander why these men have failed in the test; they are grouped according to four factors which have influenced their result—namely:

1. *Age.*—Experience has shown that most men over 30 years of age are both slow in the rate of dark adaptation and defective in night vision. This is a general statement for practical purposes and does not hold good in every case: it is adversely affected if the soldier has an error of refraction, and it is improved if he is well educated. After 30 years of age deterioration in night vision becomes marked with the passage of every year.

2. *Defective day vision* influences night vision by errors of refraction especially in myopia, corneal nebulae, familial defects, and other ocular diseases. For convenience and simplicity, all cases whose night-vision defect is thought to be due to any of these factors are placed in this group.

3. *Intelligence* plays a part: it is noticed that officers, headquarters companies, and the more intelligent types of men do well, whereas the man of the labourer class often fails because he does not grasp the significance of the test. The result, however, is not vitiated, as this is not the type of man one would choose for night operations demanding initiative. Careful investigation has shown that environment plays little part: it does not seem to matter whether a man is town-born or country-born, but the opinion was formed that miners were rather better than most of their class.

4. *"No explanation"* has sometimes to be noted when a man persistently fails and when none of the previous factors are in evidence. It may be due to steamy goggles or malingering.

When the unit report is complete it is sent to the commanding officer, and a star is placed against the names of men who are dangerous in their present military occupation—e.g., carrier drivers. An example of such a report is as follows:

Subject: Analysis of Night-vision Tests

To: Officer Commanding,
The Blankshire Regt.

I have the honour to forward the analysis of night-vision tests of your command, carried out on ....

Number tested	656	(622)
Number with excellent night vision—above average..	373	(298)
Number with poor night vision—below average ..	70	(80)

(Figures in parenthesis are those of another unit for comparison)

Assessment

(*a*) 5/5 is excellent, and indicates particular suitability for night operations.

(*b*) 0/5 is bad. Such cases are underlined in red, with a probable explanation written in red ink alongside.

(*c*) A star indicates that the soldier is dangerous in his present military occupation, which should be changed. (Very careful consideration is given to these cases.)

Remarks

The following factors influence the result of night-vision tests:

(1) *Age.*—Poor results are normal over the age of 30 years, especially if combined with day-vision defects.

(2) *Intelligence.*—Sometimes a soldier does not co-operate, although every encouragement is given. Poor results are always repeated.

(3) *Defective Vision.*—Soldiers wearing spectacles, etc., are always night-vision defective.

(4) *" No Explanation."*—Indicates a possible technical defect, such as steamy goggles, undue fatigue, etc.

Analysis of Night-vision Defectives

Number defective due to age	18 (37)
" " " " intelligence	14 (19)
" " " " vision	30 (22)
Number of men in whom no cause was obvious ..	9 (2)
Number who are dangerous in their present military occupation	1 (5)

It is interesting to note that in one unit two starred drivers had previously had minor accidents at night, a fact which emerged after their night-vision examination.

Results

The results of night-vision examination must always be viewed in their proper perspective, with a due sense of appreciation of a man's general training and efficiency. Failures must be repeatedly tested before being condemned, and change of occupation recommended only when the soldier himself, having a lack of confidence at night, has failed on the test and holds a responsible position. It is not difficult as a rule to detect the malingerer: the test is completely new and unfamiliar to him. Table II shows results of mass examinations, conducted by various surgeons:

TABLE II.—*Infantry Brigade. Percentage Analysis of Night-vision Tests*

Unit	Total	Over Average	Under Average
Regiment A	100%	31%	7%
" B	100%	29%	11%
" C	100%	32%	11%
" D	100%	33%	14%

Here it is seen that the over-average percentage is strikingly constant for each regiment—namely, about 31%—whereas the figures for night-vision defectives vary somewhat.

TABLE III.—*Percentage Analysis of Night-vision Defectives*

Unit	Total	Defective Vision	Age	Intelligence	No Explanation
Regiment A ..	100%	18%	19%	22%	19%
" B ..	100%	39%	21%	26%	14%
" C ..	100%	33%	19%	25%	25%
" D ..	100%	31%	44%	14%	12%

From Table III it will be noticed that Regiment A has a lower proportion of men who are defective on account of day-vision defects than has Regiment D; these regiments also show parallel figures where the night-vision defect is due to age. In point of fact, Regiment D was a regiment composed of older men and of lower grade than Regiment A, which was a battalion of young men. Regiments B and C may be taken as examples of an average unit.

In this command no treatment has been undertaken for night-vision defects; and apart from the remedy of day-vision defects it is difficult to see how the above figures could be altered. Up to date about 10,000 cases have been examined, and results of analysis comply with those figures obtained for a brigade.

Summary

An analytical and statistical report of night-vision tests in the Army is presented.

The method used, in this command, of making practical recommendations to unit commanders with a view to increased efficiency of night operations is described.

My thanks are due to brother officers who have done so much of this tedious work, Majors C. Heath and S. Smith, and Capt. I. Aubrey, *M.C.*; also to Brigadier Sir Stewart Duke-Elder for his encouragement and advice.

BAGASSOSIS

FURTHER NOTES OF FOUR CASES

BY

J. A. GILLISON, M.B., Ch.B.

AND

F. TAYLOR, M.B., B.S.

Drs. Castleden and Hamilton-Paterson described in the *Journal* of Oct. 24 (p. 478) "an industrial lung disease" which they called "bagassosis." Four men, all from the same factory and suffering from this condition, have been seen by us; two of them were the same as Cases III and IV discussed by the above contributors. Our interest was aroused, first, when one of the men related a series of symptoms which did not fit into any well-known clinical picture, and, secondly, when he remarked that several other men who had worked on his machine—a "bagasse-shredder"—had shown identical symptoms. We therefore asked to see these others.

Characteristic Symptoms

In reviewing our cases—their histories, symptoms, and clinical findings—we were struck by the close similarity existing between them, and by certain outstanding features which appeared to characterize this condition, hitherto unknown to us. These typical details seem worthy of additional emphasis, and are set out as follows:

(1) Each man showed an "incubation period" of approximately the same length, as the time of exposure to bagasse dust before the onset of acute symptoms was from two to four months in all cases.

(2) The acute phase of the illness was of sudden onset—e.g., one was riding home on his bicycle feeling quite well, when, 20 yards from his door, he suddenly felt "winded" and started coughing violently, reaching home with difficulty. Another, at work, "suddenly felt a tightening feeling across the front of the chest, and a severe hacking cough came on."

(3) The cough was particularly violent and continuous for several days.

(4) The sputum was described by the four men in the following colourful phrases: "Dark, and looked and tasted like rotted bagasse" "Green, blue, and dirty, with a foul smell." "Dark and yellow, with a burning taste." "Like manure."

(5) Three men described severe retrosternal pain coincident with the onset of cough and dyspnoea. This was aggravated by movement, and in one case was so severe as to stop his turning over in bed.

(6) All complained of great weakness, which continued for months: one, when "walking to the bus, had to keep stopping for support, was as weak as a kitten, and wished he were dead." Another "wanted to lie down, was hardly able to work at all, and thought he would collapse." Still another, after returning to work, was unable to go up the incline to the station platform.

(7) Less specific, but equally marked in each case, were mental depression and loss of weight and appetite.

Our physical examinations revealed nothing different from the findings of Drs. Castleden and Hamilton-Paterson. It was brought out, however, that exercise tolerance still remained decidedly poor in three of the men, long after the acute phase had passed. (One patient, Case III of previous paper, was noticed to have a central scotoma on the right, due to retinal atrophy—? incidental.)

Results of Investigation

Our investigations, less numerous than those made by Drs. Castleden and Hamilton-Paterson, consisted of *x* rays, bronchoscopy, and bacteriological examination of sputum and bagasse. These were kindly carried out at the London Chest Hospital by Drs. F. G. Wood, H. V. Morlock, and S. R. Gloyne respectively. All our cases were seen and investigated only in the later stages—1 to 1½ years after the acute onset.

In one case only was there decided x-ray evidence of disease. This was in the same man described by Dr. Castleden as his Case IV, whose x-ray film was reproduced as Fig. 8. Our film, taken three weeks after Dr. Castleden's, was identical. Dr. Castleden's interpretation is that this case "may be going to resolve or might progress to the fibrotic type of lesion seen in Case II." As the man had worked as a coal-miner for 20 years, is it not more likely that these persisting appearances are those to be expected? The radiologist reports: "General increase in striations in both lungs, the appearances being suggestive of silicosis in the reticular stage." The difficulty in interpreting radiological findings is emphasized by the fact that still another of our cases had been a coal-miner for 13 years.

Bronchoscopic examination showed: (i) Abnormal congestion of the trachea and bronchi; (ii) excessive white frothy mucus; (iii) glazing of mucosae more marked than normal. Examination of bronchoscopic swabs showed no moulds, but in one case "unidentified Gram-positive and Gram-negative bacilli"; in another, "Gram-positive bacilli only"; while a third was sterile—all organisms thought to be contaminations and not pathogenic. The crude fibre showed neither bacilli nor moulds.

An important aspect, other than the purely pathological, is the legal one. In all our cases the men had had a severe and prolonged illness, almost certainly as a result of inhaling the sugar-cane dust, and had lost many working hours. No payment under the Workmen's Compensation Act could apparently be claimed, as the disease is not a scheduled one.

It would seem that we have not sufficient knowledge of this new disease to lay down criteria by which compensation may be assessed. If Dr. Castleden's view is correct—namely, that some patients may develop a permanent lung fibrosis—the importance to the workman of scheduling the disease is clear.

Summary

Some characteristic symptoms following inhalation of bagasse dust are described; difficulties of radiological interpretation and the importance of scheduling the disease are mentioned.

Medical Memoranda

Unusual Skin Sensitivity

The following recent case of abnormal skin sensitivity may prove of interest.

Mrs. A., aged 35, saw me first in Dec., 1940, at my infirmary skin clinic. At that time she was suffering from a reactive eczema which she had had periodically since the age of 7. On going into her history I found that the eruption was much worse 7 days before a period, and began to clear when the period started. With this information I put her on to stilboestrol through her doctor, and I did not see her again until June 23, 1942. She then told me that for the past 18 months she had done very well, and eventually had ceased taking the stilboestrol, but now had a recurrence of her original eczema. I considered merely putting her back on to stilboestrol, but thought that oestroform might be used, as I have known a number of cases respond well to it. She was then ordered 20,000 units of oestroform twice weekly in the 7 days preceding a period. She had these, and a week later the eczema erupted violently, and there were swellings of the hands and feet and other parts, which alarmed her greatly. This reaction, however, lasted only a few days and then resolved, with vast improvement in the eczematous lesions.

I saw her on Sept. 10, when she gave me this remarkable history: While the previously mentioned reaction was taking place she felt her right leg above the knee on the inner side to be extremely hot, and when in bed she pressed the fingers of her left hand against it to relieve the condition. In the morning she was astonished to find that the outlines of all her fingers were visible on this area in the shape of a vesicular eruption. The thumb area was not so well marked, as pressure was not applied with the whole length of this, but all the other fingers were clearly outlined; in addition to this, it was a point of great interest to me to notice that where the wedding-ring had been pressed against the leg the skin was perfectly normal and appeared as an ordinary white band. The marks were clearly visible to me a fortnight later.

This, then, must be a case of sensitivity to her own skin with negative sensitivity to the gold of her wedding-ring, and, I am afraid, merely serves to add to the confusion in the problem of skin sensitivity.

ALLAN BIGHAM, M.D.,
Hon. Dermatologist, Bradford Royal Infirmary.

Reviews

DISEASES OF METABOLISM

Diseases of Metabolism. Detailed Methods of Diagnosis and Treatment A Text for the Practitioner. Edited by Garfield G. Duncan, M D (Pp 985; illustrated $12.00 or 60s.) Philadelphia and London: W. B. Saunders Company. 1942.

A generation ago medical textbooks contained a section entitled "Diseases of Unknown Causation," and a little later some of the items under that heading were separated off as "Diseases of Metabolism," adopting a word introduced into physiology by Michael Foster. That this sturdy infant has now reached adult stature is demonstrated by the book before us, which contains over 900 pages. A quotation from Leonardo da Vinci, "The body of everything that takes nourishment dies and is constantly reborn," strikes the keynote. Controversial matters are for the most part omitted, and certain limitations have been adopted as necessary. Thus endocrine disturbances have been included only when directly related to generally recognized metabolic diseases. On the other hand the subjects of nutrition and deficiency diseases find a place as being definitely linked with the subject of metabolism. An account of recent work on the lesser-known vitamins is included.

Of recent years increased attention has been given to mineral metabolism and water balance, and these two topics receive full consideration. The discussion of mercury as a diuretic may be taken as a sample of the style of the book. It is pointed out that although mercury is a general protoplasmic poison the obvious lesions are usually restricted to the gastro-intestinal tract and the kidney, where it causes epithelial necrosis. Diluted to an innocuous concentration in the blood stream, it passes into the glomerular filtrate of the kidney. As water is drawn from this filtrate by the tubules the concentration increases enough to coagulate the epithelial protein and thus checks reabsorption. The alimentary lesions are probably due to a similar process. These lesions are quite superficial and do not involve the basement membrane, so that they are reparable even when quite extensive. This is a useful reminder, however, that when we use mercurial diuretics we are invoking the aid of a pathological process. An interesting statement is made concerning diabetes in childhood, to the effect that in 90% puberty occurs at, or slightly earlier than, the normal time. This certainly would not have been true fifteen years ago. In the early days of insulin therapy, when a diet very restricted in carbohydrate content was the rule, these children were almost always wizened and late in developing. The change to a more ample diet covered by sufficient insulin dosage has certainly worked a great improvement in this respect.

The book is not crowded, as some are, with irrelevant illustrations, and the bibliography is confined within reasonable limits. It will prove a valuable book of reference, and a comparison of it with Von Noorden's great work in three volumes which appeared early in the century will show how completely the outlook on disorders of metabolism has changed in less than forty years. The editor tells us of the encouragement given by Sir Frederick Banting to his undertaking of this task, and the foreword was written by Sir Frederick only a few days before his untimely death.

PICTORIAL AIDS TO ANATOMY

Illustrations of Regional Anatomy. By E. B Jamieson, M.D. Fourth edition. Section I. Central Nervous System (50 plates. 8s 6d., plus 5d postage.) Section II Head and Neck. (64 plates 15s., plus 6d postage.) Section III. Abdomen. (43 plates. 7s 6d, plus 4d postage.) Section IV Pelvis (43 plates. 5s, plus 4d postage) Section V Thorax (33 plates. 5s., plus 4d. postage.) Section VI. Upper Limb Third edition. (42 plates. 8s 6d, plus 5d postage.) Section VII Lower Limb (52 plates 10s 6d, plus 6d postage) Bound volume 60s., plus 9d. postage. Edinburgh: E and S. Livingstone. 1942.

Notwithstanding a "disaster" which befell the production of the fourth edition of Sections I to V, and the third edition of Sections VI and VII, the printers succeeded in reprinting a new issue of E. B. Jamieson's well-known *Illustrations of Regional Anatomy* before the opening of the new winter session. These have been beautifully executed; 242 colour-blocks have been added, and some of the finer details of dissections have been reproduced on an enlarged scale. The colour in most of the illustrations is a great help in distinguishing the different parts, and with the very closely printed labels it materially helps in accomplishing the desired result—namely, "anatomy made easy." There is little to criticize in a work so carefully and accurately carried out. Attention may, however, be drawn to Section III, Plate 25, in which the coeliac and superior mesenteric arteries appear to be given off from the unopened abdominal aorta, whereas the "right" renal artery is depicted at its origin from the interior of the aorta; the right half of the aorta is shown below as it would be seen in a sagittal section, but no indication is given of the change from the sectioned to the unsectioned parts. A similar vagueness is present also in Section III, Plate 5, in which the arrow pointing to the blank space which represents the anterior wall of the femoral canal reminds one of the old query whether the term "canal" denotes the watercourse on which the ships sail or the earth-channel which confines the water. In Section VI some of the figures err in being too schematic, and are thus unreal. The general impression, however, which is given by the work is of reliability and an accurate knowledge of what the student needs in order to understand the relations of the dissected parts and obtain a visual knowledge of the general structure of the human body.

DENTAL SURGERY AND PATHOLOGY

Dental Surgery and Pathology By Sir J. F. Colyer, K.B.E., LL.D., F.R.C.S., L.D.S., and Evelyn Sprawson, *M.C.*, D.Sc., M.R.C.S., L.D.S. Eighth edition. (Pp. 1,067; illustrated. 45s.) London, New York, Toronto. Longmans, Green and Co. 1942.

The task of revising the original work of Sir Frank Colyer was undertaken by Mr. Evelyn Sprawson. It was a notable and important achievement, because since its first publication this has always been the textbook on dental surgery most used by the student. The new (8th) edition has incorporated recent researches and advances both in the theory and in the practice of dentistry, so that the vade-mecum of the student becomes the reference book of the practitioner. In this respect the comprehensive index at the end is most helpful. The early chapters are almost entirely devoted to the various anatomical abnormalities of the teeth and jaws—a dull subject, but one which must be digested by the student to appreciate the principles of orthodontics. These are clearly and simply illustrated, emphasizing the methods of treatment by extraction rather than by the appliances of some teachers. The latter two-thirds of the book has been almost completely rewritten since the reviewer was a student some twenty years ago, and leaves him impressed and even amazed at the painstaking analysis of recent research and published articles. The aetiology and pathology of dental disease are described in detail, and although space has restricted the discussion of treatment in some instances to general principles, there has been no omission of any recent therapeutic measure that has proved useful in practice.

The volume now runs into over a thousand pages and is heavy and uncomfortable to hold. The authors might well consider dividing the work into two volumes in a later edition.

WAR NURSERIES

Young Children in Wartime: A Year's Work in a Residential War Nursery By Dorothy Burlingham and Anna Freud. (Pp. 81. 1s. 6d.) London: George Allen and Unwin, Ltd. 1942.

To the harassed medical officer bewildered by the multiform difficulties arising out of nursery homes this report will come as a blessing. Not only does it describe the wholly admirable administration of a group of three nurseries (two residential and one for day children), but it includes—with an endearing lack of technical terms—an account of child development and psychopathology so simple and yet so profound that the unlearned in psychology and the experienced psychiatrist alike may read it with enjoyment and profit. The four sections deal respectively with statistics, nutrition, medical report, and a survey of psychological reactions. In the last of these sections, which occupies two-thirds of the whole booklet, the behaviour on which deductions are based is demonstrated with the clarity of a microbiological film. It is clear also, in spite of the restraint shown by the authors, that these nurseries are run with an efficiency, devotion, and human understanding that should serve as a model for others, whether in time of peace or of war.

Notes on Books

TASSMAN'S *Eye Manifestations of Internal Diseases* (Henry Kimpton; 48s.) deals with ocular disease not from the point of view of the physician but from that of the ophthalmologist seeking for a general factor in eye disturbance. The text is encyclopaedic in intention but not in execution. A large number of conditions are listed, but the description both of the conditions and of their correlations is sketchy. The book is essentially an elementary textbook of ophthalmology from which the surgical aspects have been omitted. Its chief value lies in the fact that it stresses, rather more than the standard textbooks, the general basis of ophthalmology.

The Board of Education and the Ministry of Health have issued an attractively illustrated booklet, entitled *Not Yet Five*, on the subject of children over 2 in wartime nurseries. The Departments hope that this will serve to enlighten the public generally on the work of the nurseries, and especially to create an interest in it among girls and women of 16 and upwards who are free to take up nursery work. The pamphlet can be obtained from H.M. Stationery Office through any bookseller, price 3d.

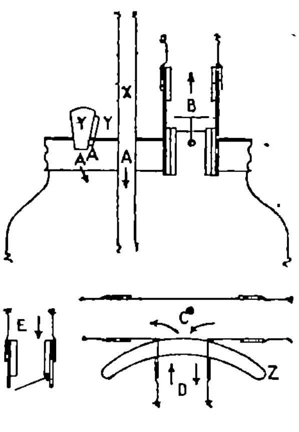
Preparations and Appliances

THE SERVICE ETHER VAPOUR APPARATUS

Capt. J. C. H. BROWN and Capt. W. E. COUNIHAN, R.A.M.C., send the following description:

This apparatus, originally called by its designer (J. C. H. B.) the "anaesthetist eliminator," was, as its name suggests, designed to be available for the single-handed medical officer when he had to administer the anaesthetic and then do the necessary surgical procedure. It has not been used as such by me (W. E. C.) in a military hospital, but I find uses for this apparatus, particularly in rush periods. A patient can be left with a degree of safety, and anaesthesia still continues. The sketch I hope will spare a deal of explanation, but the main points are as follows:

Ether container, a 2 lb. jar with a metal screw top. This lid has three inlet (air) perforations (A); one carries a metal tube (X), which can be adjusted to the level of the ether (liquid), the other two being controlled by corks (Y). The vapour is carried to, and away from, the patient by a 3/4 in. bore rubber tubing, which holds in its length a T-shaped metal angle (C), attached to which is an ordinary airway (D). The latter is guarded by a dental-wax mouth-cover (Z), to which head harness may be attached.



The valves are constructed in metal tubes, the inspiratory valve (tube B) being fixed to the metal screw top, the expiratory valve (tube E) fitting into the rubber tubing. The inspiratory valve is a light metal disk lying on a hub in its tube, and being kept in position by a metal pin and shot weight; the former is carried through a metal bar which extends across the lumen. The expiratory valve is a rubber disk screwed to a hub in its metal tube.

The apparatus can be assembled anywhere by a tinsmith, the necessary metal parts and valves being soldered in position. These valves are such that the apparatus is self-administering on inspiration, giving an intermittent flow of vapour with practically no rebreathing. The inspiratory valve unit is an original pattern so far as I can discover, and it will not easily corrode.

The designer (J. C. H. B.), of the Cunard White Star Line, induced patients with open ether, brought them to the stage of surgical anaesthesia, connected the apparatus, and controlled it thenceforth with a sterile forceps, and found it satisfactory. The apparatus has been used by me (W. E. C.) for induction by open ether, or pentothal and open ether, anaesthesia being continued by the patient and the depth controlled by the air entries. When anaesthesia is established the next case can be dealt with confidently without continuous personal attention.

THE Rh FACTOR AND ISO-IMMUNIZATION

The discovery that iso-immunization—the immunization of one member of a species by an antigen lacking in himself but present naturally in another member of the species—may cause a haemolytic reaction in the recipient of transfused blood compatible according to the original A–B–O system of groups was bound to be of great importance at a time when so many blood transfusions are being given. But when the story is as exciting as is that of the Rh factor—the red-cell antigen most commonly involved in iso-immunization—and of the establishment of iso-immunization as the cause of erythroblastosis foetalis, the widespread interest shown in Rh by the medical profession and press is only to be expected. It provides one of the most fascinating chapters in the history of laboratory achievement, and began by the finding of Landsteiner and Wiener that the serum of a rabbit injected with the red blood cells of a rhesus monkey agglutinated the red cells of most, but not all, human beings. The positive and negative reactors are called Rh-positive and Rh-negative. Before long, antibodies in the serum of certain recipients who had reactions after blood transfusion were identified as anti-Rh. These recipients were all Rh-negative and either had received previous transfusions or were women who had recently been pregnant. They had been immunized by an earlier transfusion of Rh-positive blood, or, in parous women, by Rh antigen present in the foetus, so that transfusion with Rh-positive blood—and 85% of donors are Rh-positive—was almost certain to lead to trouble. When these reactions were observed in the mothers of babies suffering from erythroblastosis foetalis the connexion of iso-immunization with this condition was quickly established. It results from the iso-immunization of the mother by a red-cell antigen—in most cases Rh—lacking in the mother but present in the foetus and inherited from the father, and the subsequent passage through the placenta of the antibody formed by the mother to act on the susceptible blood of the foetus. These most important discoveries were all made in the U.S.A., and investigations described in this and last week's *Journal* by Boorman, Dodd, and Mollison, and by Taylor, Race, Prior, and Ikin, confirm the American work. Fortunately iso-immunization occurs in only a small proportion of the cases in which the groups of recipient and donor or of mother and foetus make iso-immunization possible; why this is so is not yet understood. Obviously the detection of Rh antibodies and the diagnosis of the Rh factor in red cells are of the highest importance in connexion with transfusions of whole blood where incompatibility due to Rh may occur, and in these cases it is desirable to give only Rh-negative blood. If the position is not certain it may be better to avoid whole blood and use plasma or serum. For transfusing an infant suffering from erythroblastosis, Rh-negative is better than Rh-positive blood; Rh-negative blood has been shown to survive longer. As the mother's blood contains the harmful antibody it should not be given. The ideal donor for such a baby would be Rh-negative, would never have had a transfusion, and would never have been pregnant. Anti-Rh has been found in the sera of women years after their last pregnancy.

Diagnosing the presence of Rh antigen and Rh antibody is a tricky business, and considerable experience is needed for success. Slide and tile techniques used by most people for blood-group reactions are very unsatisfactory in Rh work, and test-tubes are necessary. Incompatibility due to Rh will almost certainly be missed unless the direct matching of the recipient's serum and intended donor's cells has been performed in tubes; and it is advisable to seek Rh antibodies both at room and at body temperatures. With at least one serum containing Rh antibody, incompatibility with some Rh-positive donors would have been undetected if the tests had been made with undiluted serum; that reactions were seen only when the serum was suitably diluted suggests the advisability of performing the tests in the form of a titration.

The Rh factor is of great importance, and no doubt it will be shown to be the cause of many transfusion reactions otherwise unexplainable. But incompatibility due to Rh is far from being the only cause of transfusion reactions, and the antigens and antibodies of the A–B–O system of groups are potentially far more dangerous and will lead to far more reactions unless everything possible is done to avoid incompatibility. The need for careful and complete A–B–O grouping and adequate direct matching is as great as ever; enthusiasm for the new and intriguing Rh factor must not be allowed to lessen the appreciation of this need, and, actually, it ought to lead to revision of the methods used for direct matching.

PLANNING AND THE M.O.H.

When the Medical Planning Commission reassembles next week it will know what the organized groups which make up our profession think of the draft interim report which was laid before it by its various committees. Not the least important of these critical reports will be that of the Society of Medical Officers of Health, coming as it does from men and women of wide experience in administrative and preventive medicine, who are almost entirely whole-time salaried officers. There have now been published[1] not the final conclusions of the society but the recommendations which its own Medical Planning Committee has made to the branches and groups of the Society.

In certain fundamentals the proposals in this report are in line with those set out in the draft interim report of the Commission. It is recognized that the health and medical functions of the various Departments of Government should be brought within one central Government Department—a "real" Health Department. It is agreed that local departments should cover areas wider than those of many existing local authorities. Central and local unification form the administrative basis of the new order. But one finds no signs in this report of any wish to modify the existing "set-up" of local government, except by the creation of local medical advisory committees. Medical representation on local authorities or committees thereof is *not* one of the proposals. There is approval for the conception of the health centre as the focus of local personal health services. The family should be regarded as the health unit, and each general practitioner should have the care in health as well as in disease of a suitable number of persons. The family doctor would "participate" in maternity and child welfare and school medical work for the families under his charge. The number of practitioners working at a health centre would vary according to the type of area, with special arrangements in rural areas. Incidentally the authors of this report recommend that consultants should attend at regular times at health centres—a view which is not generally acceptable to the consultants themselves.

---

[1] *Publ. Hlth.*, Sept., 1942.

The principle of unification of local services under a local authority being accepted, it follows that hospital services should be regarded as an integral part of local health services, and not administratively severed from them. Thus the duty of providing hospital services would be the function of the new local authorities in co-operation with the voluntary hospitals and, if necessary, with one another. The suggestion to create *ad hoc* hospital authorities for the administration of all local hospital services is rejected as something which would cause fresh confusion in a field where integration is essential. But it is recommended that all hospitals, voluntary and local authority, should be available for all members of the community on similar terms and conditions. As later proposals show, this in effect means that both types of hospital should be open to all sections of the community.

When we come to the question of staffing, the report diverges sharply from the majority view of the Planning Commission. Naturally, the approach to this question is that of the administrator. Administrative efficiency requires, it is argued, the elimination of private enterprise, as it is called, and the conduct of such services on a whole-time salaried basis. "Hitherto the doctor has been mainly interested in the illness of his patient, but it is of the first importance that his attention should be directed to the maintenance of health." In short the report recommends a national medical and health service on a whole-time salaried basis. Complete free choice, it appears, is not regarded as essential, though the maximum free choice, it is urged, should be given to patients in the selection of their doctors within the organization provided. The words "within the organization provided" will hardly satisfy those who believe that free choice cannot flourish within the confines of a whole-time salaried service. Ample opportunities for study and research would be afforded, especially in the direction of the maintenance and improvement of health, which, it is stated, "hardly thrive in an atmosphere of private competition." There is no direct comment on the arguments advanced by the majority of those responsible for the Commission's draft report that the "cold hand of bureaucratic control," with the doctor acting under the orders of the superior officers, would be inimical to the wise and humane administration of a personal health service. Presumably that and similar arguments are rejected. But in view of the condemnation of what is called private enterprise in medicine, it would be helpful to know whether medical officers of health regard competition for the favour of superior officers or committees as involving dangers as great as those of competition to attract patients. It is clear that they are not satisfied with the existing methods of making appointments, for they go on to recommend the creation of appointments boards to advise authorities in making appointments.

The report recognizes that it is one thing to elaborate a new service and another to create a new attitude of mind. Clearly the medical profession will need a new kind of education before really effective progress can be made. Indeed, there are some who think that if the efforts of planners were concentrated on the recasting of medical education the greatest good would be achieved, even without changes of a legislative or administrative character. The difficulties of the immediate future are recognized. For example, it is suggested that during the period of transition local authorities should be empowered, after consultation with the local medical profession, to determine which method or methods of staffing they consider most appropriate for the hospitals or health centres, or domiciliary practice, in the whole or parts of their area. This proposal has its dangers. A common standard of medical service would not be achieved by creating different standards among medical practitioners. The terms and conditions of any future medical service should be determined, not between individual local authorities and local units of the profession; but at the centre between the Government and the representative body of the profession. They should be determined at the beginning and not at the end.

At the conclusion of this war a large number of young medical men without experience of civilian practice will be seeking careers at home. We must plan for their re-absorption into the country's medical services. That means we must plan now. But it should not mean, and it must not be allowed to mean, that advantage should be taken of this situation to absorb these young men into a form of medical service which, though immediately attractive to the demobilized and maybe temporarily unemployed soldier, is not the best which the Government and the doctors can work out in free negotiation.

POPULATION PROBLEMS

To notice in the same article a report on a new housing estate[1] and a criticism of the Registrar-General[2] may seem bizarre; the connexion is, however, intimate. The report of the Birmingham Social Survey Committee on a sample of families in the Kingstanding Estate in 1939 reaches conclusions not fundamentally different from those drawn by other investigators, notably Mr. Rowntree. The scale of the investigation is small (269 families), but observations relate to a period of steady employment under the shadow of imminent war, and some sensible improvements of technique have been made. Once more the hardships of families with many children under the age of 14 are made manifest. More than 50% of families with 4 or more children under 14 are living on means below the sufficiency level when an absolutely Spartan standard of necessities is used (no holidays, no amusements, no tobacco, indestructible furniture). The percentage soars above 80 when a more realistic measure is used. Of all the children under 14 years of age, 31% were in families on or below the borderline by the first and 60% below sufficiency by the second measure. In other words, large families suffer great privations—a fact which members of the families knew without statistical investigations. Hence the popularity of birth control. A recent apparently well-informed article in the *Times* suggests that neither national enthusiasm nor dictatorial brutality has really had much effect on the effective fertility of the Reich. A brutally efficient Government with spies in every house can do a good deal to check abortions and something to encourage early marriages, but little else.

Dr. Kuczynski's pamphlet is largely a criticism of the memorandum on trends of population issued as a White Paper and the subject of recent controversy in the *Times*. One of the numerous evils of war is that official publications inevitably tend to be propagandist in tone. A broad distinction between enemy and Allied statistical propaganda is that the former makes equal use of the positive untruth and of the *suppressio veri*, while the latter eschews direct lying but is certainly not innocent of suppression. The objection to the memorandum was not that any important statement in it was inaccurate but that, to a general reader, the impression conveyed by it was misleading. Whether the retort—that the document was intended not for general readers but for statisticians—was adequate is a delicate question. There is much to be said for Dr. Percy Stocks's opinion (expressed in this *Journal* on March 21, 1942) that this is not the time to ventilate grounds for remoter fears, when immediate dangers are so pressing. But Dr. Kuczynski's memoir is much too arithmetical to find many readers in omnibuses, and should be read by publicists who are daunted by mathematics. It ought to deter them from that facile optimism they are so ready to denounce in others.

---

[1] *Nutrition and Size of Family*. Report prepared for the Birmingham Social Survey Committee. (George Allen and Unwin. 2s. 6d.)

[2] *The New Population Statistics*. By R. R. Kuczynski (Cambridge University Press. 1s. 6d.)

It is obvious—to use a word which so often means "I cannot prove"—that population will decline unless the conditions mentioned in the first part of this article are remedied, and it is by no means obvious that if they were remedied the decline would be arrested. It is also, if not obvious, at least not very difficult to see, that short views are useless. It is preposterous to point to the fact that total population is not decreasing. The fundamental index —as many vital statisticians have pointed out, not least energetically Dr. Kuczynski—is whether the numbers physiologically capable of bearing children in this generation are replaced by equal numbers in the next generation. If they are not, there must ultimately be a decline which is only masked by the survivorship of those who can contribute nothing to the next generation. When Hamlet dies the play is over; Fortinbras marching across the stage with an army of supers does not affect the issue. It is arguable that, in planning a new world when the black-out curtains have been drawn for the last time, as much patient thinking ought to be devoted to the organization of life on the hypothesis that fertility will not increase, that the population will in fact decrease to a stable figure, as on ways and means of increasing fertility.

HOW MUCH VITAMIN D?

Earlier this year[1] we discussed in a leading article the important question of how much vitamin D should be given to children daily, and in particular doubted whether the official dose of cod-liver oil compound advised by the Ministry of Health was sufficient. "So far as can be made out from the label describing 'cod-liver oil compound,'" we stated, "the daily dose for children from 2 to 6 months old would supply a maximum of 180 units of vitamin D; for older children the maximum amount would be twice this." In estimating how much vitamin D an infant of 12 months would receive from various sources, we concluded that this would come to less than 500 units a day. In the 1936 *Addendum* to the pharmacopoeia the maximum prophylactic dose of vitamin D (calciferol) was given as 1,000 units a day for an infant. The concern that we expressed is now echoed by a special subcommittee of the British Paediatric Association, which has drawn up an informative memorandum on the subject. The subcommittee points out that the minimum requirement for infants and children is not known. According to the Technical Commission on Nutrition of the League of Nations (1938), infants need 400 to 500 international units (i.u.) daily, and therefore, according to this, the Government's prescription would appear to be an adequate supplement to what vitamin D is obtained from other sources. But, in view of rationing and of the wide fluctuations in the amounts of vitamin D in milk throughout the year, the cod-liver oil compound should contain the full daily requirement. The Committee on Food and Nutrition of the National Research Council of the U.S.A., and the Committee on Vitamins of the American Academy of Paediatrics, put the requirements of children from birth up to 15 years of age at from 400 to 800 i.u. daily. Eliot and Park,[2] however, recommend 800 to 1,000 i.u. daily for full-term infants. During the last ten years the prophylactic dose of vitamin D given at St. Bartholomew's Hospital has been 600 i.u. The subcommittee points out that the Government cod-liver oil compound would provide 200 i.u. daily for infants under 6 months, and 400 i.u. daily for older infants, taking the maximum dosage for the former as half a teaspoonful daily, and for the latter as one teaspoonful. It goes on to state, "It would be hard to find any authority with clinical experience to support so small a dose; moreover, it will be noted that infants under 6 months are allowed a smaller dose than older babies, which does not accord with their actual needs." It considers that a daily allowance of 700 i.u. of vitamin D would give a wider margin of safety, and suggests that a vitaminized oil should be reinforced with irradiated ergosterol—by which we presume calciferol is meant. Premature infants from birth to two years should receive a daily allowance of 1,400 i.u. The subcommittee makes the excellent recommendation that printed directions should be issued to the mother with the ration of vitamin D. This should tell her to start the oil gradually, beginning with a few drops daily when the infant is a month old, the full dose of one teaspoonful (700 i.u. daily) to be reached at the end of a fortnight. She should be told that a premature infant (i.e., one whose birth weight is below 5½ lb.) is particularly susceptible to rickets, and that the vitamin D supplement must therefore be doubled, to be given in four equal doses daily. Such a supplement should be given throughout both summer and winter. For infants weighing over 5½ lb at birth the mother should be told that the cod-liver oil need not be given on summer (presumably also sunny) days so long as the infant is out of doors morning and afternoon. A further practical common-sense and obvious recommendation is that the composition and vitamin content per dose of cod-liver oil compound should be given on the label for the information of doctors.

We need only add one comment, and that is that if the daily requirement of vitamin D for infants and children is not known exactly it would seem to be dangerous to recommend a minimum dose, and sound medicine should aim at a dose which, on the evidence available, provides a margin of safety.

JUVENILE DELINQUENCY TO-DAY

The appearance of a report on young offenders[3] was foreshadowed by a circular issued by the Home Office to magistrates sitting in juvenile courts. At the beginning of 1938 the Home Secretary decided to institute an investigation into the problem of juvenile crime, under the director of the London School of Economics, Prof. Carr-Saunders, assisted by two of its staff. A large mass of data from London and many provincial cities was collected and closely analysed, and this report gives an account of the conclusions. After a survey of the most valuable of previous investigations, which forms a useful bibliography for the research student, Dr. Mannheim discusses trends in the incidence of juvenile delinquency and the serious increase from 1933, the year in which the Children and Young Persons Act was passed, to 1938, the last year for which the statistics were reviewed. He summarizes Dr. Rhodes's earlier inquiry into the geographical aspect of the problem, and into the proportion of juvenile to adult crime. Dr. Rhodes himself deals with the present investigation under its various heads—the home, the boy himself and his age, the crime, and many other factors which enter into each case. In their conclusions the investigators lay stress on the influence of abnormal conditions in the home, especially broken families and step-parents. They find that the chance of a delinquent coming from a home with an abnormal atmosphere is three or four times as great as from a home with a normal atmosphere, if the structure of the family in both cases is normal. Where both atmosphere and structure are normal they find some association between delinquency and the condition of the home, overcrowding, and irregularity of the parents' employment. The children in the control group (a notable feature of this inquiry) had better records of school conduct and attainment and of attendance at church and Sunday school and were generally a "livelier lot" than the delinquents, who usually seem to be somewhat inferior or subnormal. The authors have not, however, found that any one factor is uniformly associated with delinquency and dissociated from innocence. They draw an interesting comparison between immunity to disease and the apparent immunity to delinquency which they found in some children living under conditions which often produced it. They indicate some lines along which a great deal of further inquiry is necessary. The psychological study which they had planned but could not carry out because of the war is long overdue. Statistical research should, they say, be regular and systematic, and the methods of treating juvenile delinquents should be continually and quantitatively investigated.

SYNTHESIS OF ASCORBIC ACID BY ANIMAL TISSUES

All the animals which have been studied, except guinea-pigs, man and the other primates, and apparently all the higher plants, can synthesize vitamin C, but there is no certain evidence as to the nature of the substance or substances from which the vitamin is formed. The structure of ascorbic acid points to a carbohydrate precursor, and it has been reported by Ray[1] and various other workers that sprouting seeds produced additional ascorbic acid when glucose, fructose, or mannose was added to the medium in which they were growing. Hopkins and others[2] found that the average ascorbic acid contents of the intestinal wall and of the liver of rats receiving a normal mixed diet were the same. When carbohydrate was the only food the ascorbic acid content of the liver immediately became higher than that of the intestinal wall. When carbohydrates were absent from the diet the concentration in the liver fell and that in the intestines rose. No satisfactory explanation of this seemed to be available. Masulin and his co-workers[3] [4] found that vacuum-distillable fractions from the unsaponifiable matter of halibut-liver oil, oat oil, grass-leaf oil, and alfalfa-leaf oil given to rats caused a high excretion of ascorbic acid. Sterols, proteins, and sugars did not do this. The substances which caused the increase were so varied in structure (many terpene-like cyclic ketones and various aliphatic compounds) that it was concluded that they were not precursors of the ascorbic acid excreted, but that they stimulated the formation of ascorbic acid from intermediary metabolites. Smythe and King[5] found that tissue slices of liver, kidney, and brain, and muscle extracts or homogenized muscle, from rats which had been given chloretone for at least two weeks, showed evidence of ascorbic acid production *in vitro*, while those from normal rats gave less or no evidence of synthesis. Liver and kidney tissue were more active than brain or muscle. Maximum synthesis was obtained with a substrate consisting of a mixture of pyruvate, glyceric aldehyde, and hexose diphosphate. Mannose, glucose, and *l*-keto gulonic acid were ineffective. The quantities of ascorbic acid synthesized by tissues *in vitro* were enough to account for a large part of the ascorbic acid excreted by chloretone-fed animals, which was often as much as twenty times the amount normally excreted.

NIGHT VISION

It is now recognized that dark adaptation and the determination of threshold values give but a partial analysis of what Air Commodore P. C. Livingstone[6] terms "night visual capacity." The appreciation of form in low illumination is of considerable significance, and is to a great extent a psychological act, some people guessing or construing the form fairly readily, while others do not become aware of the form unless they have much more data at their disposal. These are points of obvious importance in the selection of men in the flying Services. Rigid testing by apparatus for some particular function rather than for the sum total of night visual capacity has therefore proved insufficient. Livingstone describes an apparatus in use by the R.A.F. which is constructed so as to give an approximation to natural conditions rather than to test isolated functions. Perfect muscle balance, at one time regarded as an absolute requirement, has in actual practice proved to be less necessary than it was previously held to be. The experience of one-eyed pilots is in itself sufficient criticism of the older conception, and Livingstone, discussing the components of the physiological consequences of binocular muscle balance, draws a distinction between stereoscopic appreciation, depth perception, and parallax. Here, too, apparatus designed to test these functions in conditions of night landing had to be designed, and Livingstone stresses the fact that, whilst acquired heterophoria is a definite cause of inconsistency in landing aircraft, the inherent type exercises an adverse effect only when the condition is pronounced. Views on the physiology of night vision appear to parallel those on colour vision. When the problems of colour vision as applied to the exigencies of navigation and railroads were first formulated, serious mistakes were made in transferring laboratory findings to the complex situations actually present in life. Further experience made it necessary to evolve tests more conforming to natural conditions, with the result that standards of rejection became more stringent in some directions and less stringent in others As Major B. W. Rycroft observes in our present issue. "The results of night-vision examination must always be viewed in their proper perspective, with a due sense of appreciation of a man's general training and efficiency." In his analysis of failures Rycroft refers, under the heading of "No Explanation," to "steamy goggles or malingering." That one of the causes of such failures is a psychological disorder was shown in the elaborate study undertaken by Wittkower and his colleagues, the results of which were published in this *Journal*[7] just a year ago.

We much regret to announce the death of Sir Norman Walker, late President of the General Medical Council.

FOOD POISONING

BY

Sir WILLIAM SAVAGE, M.D., B.Sc.

When we talk about food poisoning we mean acute poisoning. In a technical sense typhoid fever, if the infection is carried in food, is food poisoning, but by usage we mean by food poisoning an illness of comparatively sudden onset following the ingestion of some infected type of food.

Classification of Causative Factors

As regards causation the first is the inherent group—i.e., foods which are inherently poisonous. This applies to many fish found in Continental waters. Ergot could be included, and the best example is, of course, the mushroom, certain types of which are inherently poisonous. The second group consists of comparatively simple chemical poisoning, such as by lead and zinc. I have had to do with an outbreak of poisoning which was due to zinc containers used for cooking apples. A number of cases of antimony poisoning have occurred owing to lemonade and other soft drinks being made in enamelled vessels in which antimony has been used. Lead poisoning among cider drinkers used to be common in certain parts of England, and was, indeed, called Devonshire colic. I have come across cases of poisoning caused by the accidental inclusion of belladonna among the sage with which a hare had been stuffed. Those are all examples of chemical food poisoning. You can recognize them, by the special symptoms of the particular chemical—lead, antimony, or zinc, as the case may be—which is involved, and, as a rule, by the short incubation period.

The third group is the large class of bacterial poisons. I have not space to say more about the first two groups, but will deal here with the bacterial group. We can divide the bacteria into four types. The commonest are the various members of the Salmonella genus; then comes a small second group caused by allied organisms, such as those of dysentery. Mr. Bruce White and I first showed that two or three outbreaks were caused by dysentery organisms, and a few years ago a food-poisoning outbreak due to ice-cream which I investigated was found to be due to the Sonne dysentery bacillus. The third group includes certain organisms, now becoming rather important, which act by producing toxins which cause food poisoning. The commonest of these are certain staphylococci—not all staphylococci, but some of them. A few streptococci are also known to have produced this peculiar toxin, and it is fairly certain that there are other organisms with this property. There is an inclination to ascribe many outbreaks of food poisoning to *B. proteus*. Whenever you get decomposing food you invariably find this organism, and the natural tendency is to suppose that it is the cause of the poisoning; but in the very rare instances when it is the cause this is only because the particular strain involved produces such a special toxin, and I believe this very rarely occurs. The fourth group is *Clostridium botulinum* (botulism).

I want to say a word about the things which do not cause food poisoning, and particularly to emphasize that putrefactive organisms do not cause such poisoning. In the lay press, and sometimes, rather disgracefully, in textbooks, we still hear of ptomaine poisoning. There is no such thing as ptomaine poisoning. The concept arose in this way. It was found that when meat putrefied badly crystalline alkaloidal bodies were formed which, when injected into laboratory animals, brought about death with extreme rapidity, and it was assumed that these ptomaines were the cause of food poisoning. This is incorrect. They are late degradation products of food putrefaction, and no one would care to eat meat when it had reached that stage. Further, these effects were produced by *injecting* animals, whereas if the ptomaines were fed to the animals *by mouth*, which is the way poisoning develops, nothing in particular occurred. Putrefaction as such is not a cause of food poisoning. Food poisoning is always due to specific causes—e.g., specific bacteria.

Staphylococcus Food Poisoning

Within the last few years it has been recognized that certain staphylococci can produce food poisoning. They may be contained in any vehicle, but the records show that more than half of these outbreaks arose from cream cakes, éclairs, and things of that kind. The first described outbreak was in the Philippines and was due to infected milk. Cream or custard fillings have been responsible for well over half the number of these outbreaks.

The interesting point about staphylococcus poisoning is that no particular type of staphylococcus is responsible. One cannot say, for example, that the haemolytic staphylococcus acts in that way more than any other type. It is not a specific type. We all know that staphylococci produce a number of different toxins such as haemolysin. These particular strains—and there are comparatively few of them—produce another kind of toxin which we call enterotoxin. Why some staphylococci produce enterotoxin and others do not, nobody knows. They do not constitute a particular group which one can type out and say that these are food-poisoning staphylococci. We know that the presence of starch enhances the virulence of the toxin, and we can take an organism of very low potency and increase its potency by growing it in a starch medium. We know that it produces these effects because we can demonstrate them in sterile filtrates. We do not find this type of food poisoning with merely the presence of a few staphylococci, but usually only when the organisms are present in considerable numbers.

In the early days this association was doubted, and it was only possible to prove it by the fact that volunteers came forward to drink a cultured broth filtrate. Drinking, perhaps, 15 to 20 c.cm. of this filtrate, a considerable proportion of them developed the symptoms of staphylococcus food poisoning. These are, generally mildish—nausea, vomiting, and diarrhoea. Having proved it in that way, it was found that if rhesus monkeys were fed on this filtrate they also developed vomiting, but they are not quite so susceptible as man. Lately (this is of practical importance if one is dealing with an epidemic) a reliable test is to make an intraperitoneal injection of the filtrate into young kittens, which show characteristic symptoms. There are bouts of vomiting, general distress, and usually death within a few days. Volunteers, or a monkey, may not always be forthcoming, but we may be able to get a kitten and inject a fair dose of the filtrate intraperitoneally.

The same facts apply to other organisms which produce this type of outbreak. *B. proteus* and streptococci have been mentioned, while outbreaks have been ascribed to *B. coli* and in one or two instances to sporing aerobes. In any individual outbreak such an association can only be accepted with considerable reserve. Not only must the organism be present in large numbers in the implicated food but it must be proved to be a strain which produces enterotoxin. While the demonstration of enterotoxin by the kitten test is suggestive that the strain which produces it is potentially a cause of food poisoning, we are not yet in a position to assert that proof is complete that the strain was responsible for a particular outbreak. Probably enterotoxin production, based on the kitten test, occurs with strains which never cause food poisoning. Quantitative factors enter into the question, and usually the presence of very large numbers of the enterotoxin-producing strain seems to be an essential factor in the ability to set up food poisoning. This toxin is heat-resistant.

I would emphasize that one of the most important facts to ascertain in investigating food-poisoning outbreaks is the interval between the eating of the food and the onset of symptoms. It is one of the vital clues to the type of food poisoning to be investigated. If you have persons who are ill twelve, fifteen, or twenty-four hours after taking food you can be certain you are not dealing with a toxin outbreak.

So much for the staphylococcus type, which may be encountered anywhere in connexion with the feeding of troops or in civil life and which seems to be getting more widely recognized and possibly more common.

Salmonella Food Poisoning

I pass to the Salmonella type. This type used to cause about 70% of the outbreaks in Great Britain. Those of you who are bacteriologists know that there are a great many types of Salmonella. When I started to work on food poisoning forty years ago there were three known types. There are now over eighty recognized types of Salmonella, each said to be different from the rest. It is necessary to remember that only some of them cause food poisoning. Some cause disease in animals only, others in man only, and some cause disease in both man and animals, and it is the last which are responsible for food poisoning. For example, *B paratyphosus* B causes paratyphoid fever but not food poisoning, except possibly in extremely rare instances. In the same way *B. equii* causes disease in horses but not food poisoning. The types which produce food poisoning in man are types which are responsible for disease in both man and animals.

This is not a public health lecture, and I am not going to say more about the large numbers of types except that they are important in later on eliciting the source of the outbreak because each type tends to have its particular habitats. To mention but one example. The Dublin variety of *B. enteritidis* is a bovine type and occurs mainly in calves. That is the type which may be found in milk; and there have been a number of food-poisoning outbreaks from milk due to this strain. On the public health side it is exceedingly important to discover the particular strain, but from the immediate practical point of view it does not matter; they all cause the same symptoms. It cannot be said that one type produces one type of symptoms and one another. True, *B. enteritidis* (Dublin) as a rule causes a mild type, but clinically and pathologically they are indistinguishable in their effects.

There are the following reasons why Salmonellas are so much concerned with food poisoning. The types that cause it are undoubtedly gastro-intestinal irritants, setting up inflammation of the stomach and duodenum and the first part of the tract beyond, and these show redness and signs of irritation. They produce heat-resisting toxins. They grow rapidly on suitable food and, doing so, cause no physical changes in the food. Obviously an organism which can camouflage itself in that way is much more likely to cause food poisoning than one that gives rise to an odour.

Botulism

Botulism is entirely a thing on its own. There are two well-recognized types—A and B—and there is also a C type. It is necessary to remember the types, because if an outbreak of botulism occurs it is of no use to give B antitoxin to a person who is down with Type A. *Cl. botulinum* is a sporing anaerobe which produces perhaps the most powerful toxin we know. There are three things to consider—the bacillus, the spore, and the toxin; and botulism is best understood by examining the salient points of each of these, including the relative resistance. The bacillus and its toxin show no particular resistance to heat. The bacillus is killed, like any non-sporing bacillus, by twenty minutes or so at 60° C. The toxins have no special resistance to heat, but the spores are among the most resistant spores we know, therefore they are apt to survive in heated foodstuffs. The spores as such are not toxic, and if one takes a million spores and washes them so that they have no toxic element, animal experiments suggest they can be swallowed without hurt, provided conditions are not such that they can turn into the vegetative form. Under favourable conditions the bacillus produces toxins which are able to be absorbed from the alimentary tract and to exert their influence on the nervous system. The bacillus is a true anaerobe, and therefore occurs under anaerobic conditions. It is a natural soil inhabitant and, curiously enough, it is found more often in virgin than in contaminated soil. A great many years ago I sent numerous samples of soil from England to Professor Mayer in California, and spores were found in five out of about eighty.

The earlier outbreaks of botulism were in connexion with foods like ham, bacon, and sausages. In a bacon factory the hams are placed one on top of the other; they therefore do not get much air, and if any are contaminated with infected soil the bacillus may grow and produce its toxins. Then there was an alarming wave of botulism in the United States in connexion with canned foods, particularly in California, where the soil is considerably contaminated with this organism. In consequence the factors of heat resistance of this organism have now been worked out very thoroughly, and canners are told in regard to each product exactly to what extent to heat so as to be sure of killing the organism. This varies with the kind of food: for example, lower temperatures are permissible with acid foods. In consequence this danger from commercially canned foods has been removed. The bacillus is a proteolytic organism, which means that it decomposes proteins and breaks them down, giving off an offensive odour. A sour sort of smell is characteristic. It is not invariably present, because it is possible to have a stage at which the proteolytic changes are not sufficiently advanced to give obtrusive signs, although enough toxin has been produced to render the food very poisonous. As a rule both changes are present together.

The Loch Maree outbreak of botulism was due to sandwiches containing wild-duck paste. The eight people who ate those sandwiches died. The cook said she did not notice any changes in the paste, which is natural because wild duck has an odour of its own and, not being a technical person, she might not easily notice any difference. But when, in the laboratory, we inoculated tins of the paste with *Cl. botulinum* and incubated them, we could later readily detect definite changes.

Incidentally, the decomposition changes explain why we have a considerable number of single cases of botulin poisoning. The woman of the house opens a tin, notices that it does not appear good, but takes one spoonful herself to clear up the point. She discovers that it is not sound and throws it away. She dies, but the other members of the family are unaffected.

The organism acts on the peripheral nervous system; it is not a gastro-intestinal irritant. In the initial stages in certain cases there may be gastro-intestinal symptoms—some nausea, vomiting, and diarrhoea—for the first twelve or twenty-four hours, but these pass away. These symptoms are probably due either to a mixed infection or to the proteolytic products causing slight gastro-intestinal disturbance and are not part of the toxic action. The most characteristic symptoms are the following: disturbance of vision appears early, including dimness of vision, mydriasis, diplopia, and loss of reflex to light stimulation; later there is complete loss of accommodation. Another group consists of a feeling of throat constriction and difficulty in swallowing and talking. There may be complete paralysis of the pharyngeal muscles. Eventually there is complete aphonia. General muscular weakness is a characteristic feature, while there may be incoordination of muscle movement. Inhibition of the secretions is characteristic, and especially so is a dry mouth and pharynx.

It is of value to realize that certain symptoms are not found. While in the initial stage diarrhoea may occur, the characteristic feature is marked constipation, and there is an absence of any rise in temperature. Sensory disturbances, including pain, are entirely absent.

The Loch Maree outbreak was the first in Great Britain; since then there have been about three little outbreaks, and that is all we have had. Botulism is a thing to look out for, but it is very rare in Great Britain and comparatively infrequent everywhere.

(*This paper will be concluded in next week's issue*)

Deaths due to air raids are not normally reported to coroners, and therefore the figures for coroners' inquests in London are no longer a reflection of the number of unnatural deaths. During 1941 the number of deaths reported to London coroners was 8,181, a decrease of nearly 2,000 upon the year before. Of this number just over 3,000 deaths occurred in hospitals and other institutions. The number of people who met their death by accident was 1,253, being 442 fewer than in 1940. The cases of suicide—348—were 190 fewer than in the previous year. Seven verdicts of murder were returned, compared with three in 1940. The deaths due to excessive drinking numbered 44, again a decline on the previous year. In only 6 cases was the verdict returned "Cause of death unknown."

Reports of Societies

FUTURE STATUS OF PHYSICAL MEDICINE

In his presidential address to the Section of Physical Medicine of the Royal Society of Medicine on Oct. 14 Dr. P. BAUWENS discussed the status, present and future, of physical medicine.

Physical medicine in pre-war days, he said, was "rather shapeless and unsatisfactory." Efforts to enhance its position within the existing scheme of medicine and surgery proved disappointing. Many of its practitioners still worked in their departments in hospitals in subordinate positions without full staff status or direct representation on medical committees. One mistake, in his opinion, was made when the Physical Medicine Group of the B.M.A. defined not physical medicine nor its scope or functions but its practitioners, whom it described as "primarily physicians who have a specialized knowledge of the use and application of methods employed in the practice of physical medicine." To inaugurate something, no matter what, by arrogating to oneself a title which could never be accepted by common consent was no mean error.

With the war the demands for physiotherapy were multiplied, but those demands, said Dr. Bauwens, must not be interpreted as a normal development such as might be expected to result from scientific achievement. It seemed to him necessary to start planning—or, rather, replanning, because it existed already in a rather ramshackle form—the physical medicine of the future. The first step should be to recant the definition of the practitioner of physical medicine and replace it by a definition of physical medicine itself. If it was defined as that branch of medical science which was concerned with the maintenance of health and management of diseases and injuries by means of physical methods, the implication clearly was that it served all aspects of medicine and surgery. There was no branch in which physical methods, either diagnostic or therapeutic, had not some application. But physiotherapy departments ran solely by the grace of orthopaedic departments, phototherapy departments were almost exclusively dermatological, electrotherapy departments led a much-resented parasitic existence in *x*-ray rooms, and whole physical medicine departments ran entirely as centres for the treatment of rheumatic and allied conditions. This was deplorable, at least in general hospitals, but it must not be assumed that the rest of the profession were entirely to blame for these tutelages. On paper the "physical medicine man" as a specialist was "not a very attractive proposition," and the principle of "you offer nothing and so you get nothing" had been responsible for the dearth of attractive posts, and the lack of young men choosing this specialty as a career.

Qualifying Examination and Diploma

The escape from this impasse was a special qualification denoting a knowledge of physics, of the effects of physical agents on tissues in health and disease, and of anatomy and physiology applied to movement. A diploma should be created. The discontinuance of the D.M.R.E. Cambridge was regrettable in some ways, but when teaching or examining for the medical electrology part of that diploma he had felt that electrology had outgrown its usefulness as a partner of medical radiology. With the establishment of a diploma in physical medicine, institutions might become aware of the shortsightedness of separating its various sections or running them as dependencies of other departments. That physical medicine in the future would be almost exclusively institutional must be expected. Probably it would exist as special departments in hospitals, health centres, nursing homes, and in connexion with non-medical institutions such as schools and factories. The effect of a supply of medical officers with special qualifications to direct these would be far-reaching and would lead to a higher standard of work, the disappearance of pseudo-science, improved status, standardization of methods, and uniformity in teaching, all of which were sadly wanting at the present time. While Dr. Bauwens was averse from a conception which represented physical medicine as a system of medicine based on special methods of diagnosis and treatment, thus putting it on a level with osteopathy and chiropractic, he equally resented the suggestion that it was in any way menial. It sh regarded as a co-operative branch of medicine.

Some form of higher qualification was desirable to en original research. A faculty of physical medicine m formed, with the diploma as a qualification of meml and a thesis based on some original work of value as a qu tion for fellowship. In due time this might give bir chair of physical medicine, but he declined to estim gestation period.

NUTRITIONAL ANAEMIA IN CHILDREN WOMEN

A discussion on nutritional anaemia in children and considered as a wartime problem, took place at the Sec Disease of Children of the Royal Society of Medic Oct. 23.

Dr. HELEN MACKAY said that anaemia in the infant, in part, was the result of anaemia in the mother pregnancy. A drop of 10 to 15% in the mean haemoglobi in infants was certainly significant of deterioration in being. Before the war the only British investigator published average figures for haemoglobin levels for a up to the adult were Davidson and his co-workers in Abe their investigations were made during economic depressi referred to the lowest economic class. Since last autur and Dr. Lucy Wills had estimated haemoglobin levels children and 550 women, nearly all of the working class found the largest number of cases of severe anaemia age group 6 months to 2 years. Of school children exa 90% had an average haemoglobin level of about 80% some 10% were lower than even the Davidson series o children before the war. In a series of school childre 7 to 11, with a mean haemoglobin level of about 85%, ment with iron or the provision of school dinners pro a significant rise, although the rate of rise was slow. Ch of higher economic status in a London suburb wer examined, but here those who were having school dinne not show a higher haemoglobin level than the others. A group of factory girls working in a country town and in their own homes had a higher level than any other examined last winter, perhaps because they had acc country produce; but a very low haemoglobin level was in a group of nurses and students working in the countr living in either hospital or billets with no adequate ca facilities. The mean for these was actually 5.5% lowe Davidson's mean for Aberdeen in 1931-5. Many clas the community showed a levelling down of haemoglobin the outbreak of war, though this must be offset amon poorer section of the community by a levelling up as a of the disappearance of unemployment, the introducti rationing, and the system of priorities for certain grou women and children. She suggested that iron therap iron prophylaxis should be widely employed, althoug deficiency was probably not the only factor operating.

The Blood as an Index of Health

Dr. LEONARD FINDLAY said that it was a pity that so of this work was restricted to haemoglobin levels; the re count was more dependable. Recently he had had an o tunity of examining 400 children at Oxford, and found a considerable number of the estimations of both haemo and the red cells were below the normal level. This p health of the child resident in Oxford and its environ most unexpected. If it was due to a dietetic fault, the was a peculiar one, because it allowed anaemia to de while at the same time apparently—to judge from other in gations of a more general character—the height and w of school children showed no deterioration, but rathe reverse, under wartime conditions. He had been additional iron for prolonged periods, but, roughly, he found no difference between those treated with iron and not so treated. In some there was a slight rise in haemo at the beginning of treatment, but it went down after weeks, and remained down even though the same or a dose of iron were given. It was not to be concluded th highest point to which haemoglobin could be raised necessarily the physiological level. It seemed more pro that the iron exerted a stimulating effect, to which, however, the haemopoietic system soon became accustomed. He ascribed the variations he had obtained more to environmental than to dietetic conditions. His conclusion was that the blood picture was not a true reflection of the state of health of the child. A well-developed child might have even lower haemoglobin and red cell values than an ill-developed child. Nor was the blood picture necessarily an index to the iron content of the diet. Iron administered considerably in excess of the body's requirements caused, as a rule, no permanent rise in haemoglobin level. In medicinal doses iron had an irritant effect on the haemopoietic system, and the highest values reached were not maintained.

Iron in the Dietary

Dr. **Hugh Sinclair** agreed that haemoglobin values were somewhat untrustworthy. He gave the figures for nutritional surveys in Oxford and other towns, and said that the results supported Dr. Mackay's contention that there was anaemia, presumably nutritional, among women, though iron was not necessarily the whole story. Rationing had produced a shift towards bread and potatoes and other vegetables, and away from fish, eggs, and meat, so that the iron intake was probably lower than before the war. A dietitian in Oxford had made a preliminary analysis of the diets of 22 families covered by the survey in 1941 and again in 1942. The main difference as between the two periods was the introduction of national wheatmeal bread. In these families it might appear from a study of the food consumed that iron intake had greatly increased. In 1941 it was below the League of Nations standard—not a high one—and in 1942 above it, but it was probable that the considerable increase of iron in the dietary was not very relevant, because in so far as it was accounted for by national wheatmeal flour it was not available owing to the presence of a large amount of phytic acid. Dr. Sinclair also mentioned an investigation into the use of iron cooking utensils. If a potato were cooked in an iron vessel for about 20 minutes, 3 mg. of iron per helping was obtained, or slightly more than with an aluminium vessel, but if an apple were boiled in an iron vessel for only 5 minutes, 19 mg. of iron would be found in the apple, whereas with aluminium the quantity was negligible.

In further discussion Dr. R. H. **Dobbs** and Prof. R. **Ellis** mentioned difficulties in obtaining accurate haemoglobin estimation, especially in cold weather when extremities were "blue." A short paper was read on behalf of Prof. L. S. P. **Davidson** showing low figures for haemoglobin among 831 infants and children of working-class families in Edinburgh. Dr. C. F. **Brockington** considered that, contradictory as the evidence might be with regard to the absorption of iron from the diet, a measure of fortification of the dietary in iron constituents should be undertaken. Dr. J. **Yudkin** said that the haemoglobin levels for some 1,100 Cambridge school children were very good, but some Scottish results with which he had also been concerned were poorer. Dr. **Marshall** described the results of 400 estimations made on blood donors at a blood storage depot. The average figure for men was about 100%, and for women during the reproductive period of life 82%.

Dr. **Helen Mackay**, in reply, said that there might be seasonal variations in the haemoglobin level. Dr. Findlay's findings and her own differed profoundly in many respects. She had found, contrary to his experience, that the haemoglobin levels of infants could be kept up satisfactorily by giving iron, not for a period of weeks but for many months, and she believed that these findings had been confirmed in other parts of the world.

D. Skinner and C. S. Keefer (*Arch. intern. Med.*, 1941, **68**, 851) record their observations on 122 cases of *Staphylococcus aureus* bacteriaemia with a review of the literature on experimental infection in animals. Only 22 recovered—a mortality of 81.97%. There was no correlation between the season of the year or the sex of the patient and the occurrence of bacteriaemia. Most of the patients who recovered were under 30. The most frequent portals of entry were the skin, respiratory tract, bones, and genito-urinary tract. Most of the deaths took place in the first ten days. The most constant feature was high remittent fever. Secondary infection took place in 82%.

Correspondence

Prevention of Small-pox

Sir,—The letter on vaccination against small-pox from Dr Killick Millard (Oct. 31, p. 530) is typical of the prejudiced point of view of present-day anti-vaccinationists. It contains several misstatements which should be corrected.

Vaccination is not "a serious operation," and in my experience it causes considerably less discomfort and incapacity than the usual injections for immunization against diphtheria. Why the prompt and effective steps taken by the M.O.H. for Glasgow to prevent spread of small-pox in that city should have caused a "scare and public alarm" I fail to see. Has the present nation-wide campaign by the Ministry of Health to induce parents to have their children immunized produced such a psychological upset or affected productive efficiency? Again I fail to see it. Would even Dr. Millard on that account advocate discontinuance of general immunization? Surely our aims in the future, as stated by the Medical Planning Commission, must be the attainment of positive health and the prevention of disease, especially such as those mentioned with high mortality and infectiveness.

We are to-day in the position of being exposed more than ever to a country-wide outbreak of small-pox as men return from the East and travel by air becomes general. It is time that the Ministry of Health drew up a campaign for universal vaccination on the same lines as that now being conducted for immunization against diphtheria. Perhaps the two could be coupled up?—I am, etc.,

Tredegar, Mon ARTHUR HOWARD

Vitamins and Capacity for Work

Sir,—I am very interested in your leading article on vitamins and capacity for work (Oct. 24, p. 485), and especially your mention of the Mayo experiments, of which I was unaware. I have been trying vitamin B_1 on the accident-prone. I found a great deal of nervous instability among this group and wondered if it was associated with deficiency of vitamin B_1. I therefore chose ten with the greatest number of entries in the accident book, and my firm readily agreed to supply them with tab. aneurin hydrochlor. 3 mg. three times a day for 100 days. Unfortunately, at the end of two months only six of the patients were continuing to take the tablets, so I decided to note the number of their accident entries during these 60 days and also those in the preceding 60 days. The results were as follows: A, 5—1; B, 5—2; C, 7—4; D, 6—2; E, 12—6; F, 3—0. Thus all had a smaller number of entries while taking the tablets, and the total number fell from 38 to 15.

I had planned to repeat the experiment with greater numbers and with controls to eliminate the effects of suggestion, but so far pressure of work has prevented this.—I am, etc.,

Stroud. H. W. HILLS.

What is "Sterile Blood"?

Sir,—I read with great interest Prof. M. R. Drennan's letter (Oct. 31, p. 526) on this subject. I have no experience of the microscopical characteristics of "sterile blood," but the observations Prof. Drennan has made appear to correspond to certain observations I have made on the microscopical appearances of fresh blood films.

An article entitled "Examination of Fresh Blood Films, with Special Reference to Haemoconia" appeared in the *Journal* in 1907—a long time ago, but which I considered of some importance and still relative to many questions under review to-day. Prof. Drennan refers to the "spinning" of the granules of the cytoplasm in white blood corpuscles, and as the white cell breaks up these spinning bodies can be seen floating free in the blood serum. He also refers to "other highly motile bodies in disintegrating sterile blood." These phenomena and many more can be observed in examination of fresh blood films, and can be watched until complete disintegration of the corpuscular elements occurs. This I found took place in about ten days, and was dependent on protecting the film so far as possible from contact with the air. The method I used was to put a drop of blood on a cover-glass and immediately to place it on a glass slide, protecting the cover-glass from the air by ringing it with rubber solution. Examination of the film was made by dark-ground illumination several times a day. By such a method complete disintegration of the corpuscular elements could be observed with many enlightening phenomena. The film must be kept in cool surroundings or disintegration will be more rapid and difficult to follow. If Prof. Drennan would compare his observations on "sterile blood" with those of fresh blood under conditions which I have indicated, I am sure that he would find greater illumination on an important subject. He would, for example, find that not only movement of granules appears in the white corpuscles but granules appear in the disintegration of the red cells, and which also show movement and finally escape into the serum. Those have the appearance of living entities, and no doubt correspond to those which Prof. Drennan has designated as "vital elements in stored blood."

"Sterile" by dictionary definition means: (1) having no reproductive power; (2) lacking something essential; (3) lacking productiveness or fertility; (4) containing no pathogenic bacteria or other micro-organisms. Prof. Drennan will no doubt agree that "sterile blood" may answer most of those definitions, but the question to be answered is: Are those inherent vital elements, which he ascribes to stored blood, capable of reproduction and a separate entity? I believe that the process of disintegration is one of reproduction, and that disintegration is dependent on that process for its completion. The living cell contains within itself vital elements for its own destruction. It is by the release of those that disintegration eventuates. Complete disintegration of the corpuscular elements of the blood results in serum, so that a further question arises—What exists in the serum? Does it contain something which can be separated and cultivated, or has it now entered the realm of chemistry or biochemistry? There is room for further investigation, which might open many closed vistas and elucidate such problems as cancer and filterable viruses.

I will not further trespass on your valuable space, but I should enter a plea for more examinations of blood and other fluids and tissues by non-fixation and non-staining processes.—I am, etc.,

Edinburgh. FREDERICK PORTER.

Crush Injury and Anoxia

SIR,—Dr. J. Walker Tomb (Oct. 24, p. 495) has rendered great service by his analysis of the crush syndrome. There can be little doubt that the crush syndrome and blackwater fever are similar conditions; even the theories advanced in explanation are the same. Blacklock and Macdonald (1928) suggested that blackwater fever might be due to anoxaemia. Ross (1932) was unable to find an increase in blood lactic acid in malaria, and accordingly rejects the suggestion.

We have a considerable amount of information about the effects of anoxia on renal function. In the anaesthetized animal, anoxia, whether from breathing gas mixtures of low oxygen content (Toth, 1935, 1937, 1940) or from clamping the renal artery (Marshall and Crane, 1923; Barclay, 1942), usually results in a fall in urine volume, and this diminution in volume is accompanied by a rise in *p*H. In the unanaesthetized animal the usual result of anoxia is an increase in urine volume; there may, however, be a drop in volume, and here also the *p*H rises. We have no information as to the behaviour of urinary *p*H when the volume rises, but if the rise is analogous to that brought about by cyanides, then here also we should expect a rise in *p*H. The urine in the crush syndrome appears in general to be low in volume and to have low *p*H values. I suggest that the facts cited make it unlikely that the condition is due, at any rate entirely, to anoxia.—I am, etc.,

Tuberculin Skin Tests in "Influenzal Pneumonia"

SIR,—In describing an outbreak of atypical influenza pneumonia at a school Drs. H. G. Herxheimer and A. J. McMillan (Oct. 31, p. 513) do not state whether tuberculin tests were performed, and if so what the results were. With the increasing use of radiological examinations and the coming adoption of miniature radiography on a mass scale, it is becoming necessary for all practitioners to be aware of the value of the tuberculin skin tests; these are now standardized and so simple in performance that there is little excuse for omitting them in every case where the diagnosis of a chest condition is not quite clear. Could Drs. Herxheimer and McMillan assure us with any degree of confidence that these cases of "atypical influenzal pneumonia" were not due to primary tuberculous infection? It is well known that this condition often simulates "influenza" and is too often diagnosed as such. It is to be remembered that the more recent surveys in this country appear to corroborate the findings in Norway, indicating a shift to a later age group of the primary tuberculous infection.

Only two weeks ago I was forcibly reminded of the value of the tuberculin test by the finding of a negative Mantoux reaction in a boy aged 17 who had been kept in bed for nearly 5 weeks in a special chest hospital and subsequently transferred to the special unit at this hospital with a probable diagnosis of tuberculous lesion in the lung. The waste of time and anxiety caused would have been prevented by resorting to this simple test at the very first time of examination.—I am, etc.,

Queen Mary's Hospital, Sidcup. E. MONTUSCHI.

Treatment by Hypnosis

SIR,—Your interesting leader on the present position of hypnosis (Sept. 5, p. 283), besides stirring vivid personal memories, has aroused in my mind speculations of psychological and perhaps philosophical interest. My experience of hypnotic treatment dates back to the year 1910, when, under the title "Notes on a Case of Hysteria," I published in the *Journal of Mental Science* an account of a series of hypnotic experiments carried out at Gartloch Mental Hospital, Glasgow. Briefly, the subject of the experiments, a hysterical youth of 18, exhibited all the classical phenomena of true hypnosis, and would, I think, have satisfied the most exacting requirement of that condition, including those enumerated in your leader. Post-hypnotic commands, for instance, were repeatedly carried out with amnesia in the intervening period, while in the waking state. During actual hypnosis his anaesthesia was so complete that a minor surgical operation was performed upon him without movement, pain, or subsequent recollection, and a detailed account of this was published in the *British Medical Journal* of Feb. 25, 1911.

During the years 1910-14 I encountered several subjects who exhibited this extreme susceptibility to suggestion, and in whom it was possible to induce the classical manifestations of true hypnosis, including, in one case, post-hypnotic olfactory hallucinations. Subsequent experience showed, however, that this type of case was exceptional, and an attempt to induce hypnosis in the ordinary subject rarely, if ever, produced such dramatic results. Indeed, so far as objective phenomena were concerned, there was in most cases little or nothing to prove the existence of hypnosis in the accepted sense of the term, and in this I am apparently in agreement with the writer of your article. On the other hand, it was usually possible to induce a condition of mental quiescence, during which there was, or seemed to be, a heightened suggestibility, and which for therapeutic purposes proved all that was necessary.

Whether there are mental states short of true hypnosis and yet exhibiting the characteristics of increased suggestibility would seem, from the nature of the case, difficult to prove. Personally, I believe that there are, and I have been accustomed to describe them as hypnoidal states, after Boris Sidis, who, I believe, first described them. The nature, and even the existence, of such states may be a matter for speculation, but that they differ *toto caelo* from true hypnosis is, I think, beyond dispute. On the other hand, the few subjects I have encountered who exhibited the classical signs of hypnosis had certain characteristics in common. Apart from their extreme suggestibility they all gave indications of nervous or emotional instability, two suffered from hysterical attacks simulating epilepsy and were inmates of a mental hospital; one suffered from somniloquism and was undoubtedly of subnormal intelligence; while the fourth was subject to severe attacks of bronchial asthma, of which, incidentally, she was "cured" by hypnotic treatment. The conclusion I have tentatively formed is that individuals who display the unequivocal characteristics of true hypnosis are of relatively poor mental endowments, or show signs of nervous or mental instability of which their extreme suggestibility is only one form of expression.

As regards the question of surrender of personality even in true hypnosis, an amusing incident may be of interest. On one occasion I had hypnotized a girl (one of the four subjects mentioned above) in the presence of lay onlookers, one of whom, thinking to take a rise out of the girl, said to her: "Edith, with whom were you out last night when I saw you?" Quick as lightning came the rejoinder: "Oh, Miss Blank, what a question to ask!"—but she did not vouchsafe the wished-for information. This well-merited rebuff proved at least that the critical and controlling faculties were not in abeyance. As evidence, moreover, of the genuineness of the hypnosis, this patient on waking remarked on the strong scent of violets in the room, the suggestion having been made to her during "the sleep" that she would smell violets on waking. So vivid indeed was the hallucinatory impression that she was not easily convinced that there were not actually violets in the room.

With your leader-writer's general contention that success in suggestive therapy is proportionate to the therapist's own belief in it I am in complete agreement. I would go further, and say that as a rule one is acutely aware of one's power to influence a given subject, and this quite early in the treatment, and that one *knows* when one is going to be successful, and vice versa. The prepotence of the therapist's personality is, I would say, less evident in true hypnosis than in those allied conditions which fall short of it; and as suggestibility reaches its maximal degree in hypnosis, much less is demanded on the part of the physician, the patient, as it were, "doing most of it himself." Moreover, to deprive oneself voluntarily of the advantages of any particular therapy, whether hypnotic or other, merely because one has not reached a complete understanding of the mental processes involved, has always seemed to me irrational, to say the least of it. The truth would appear to be that however much the "modern physician" may wish to objectify his treatment, he is for the greater part foredoomed to failure, for in all that he performs, looks, and says, something of his personality obstinately adheres and clings.—I am, etc.,

Leeds. Psychiatrist, E M.S.

Tonsillectomy: Guillotine or Dissection?

SIR,—Mr. T. B. Jobson (Oct. 31, p. 512) discussed the relative merits of the guillotine and dissection methods of removing tonsils. He stressed the importance of removing the whole tonsil. To my mind the success of the operation in children depends largely on whether the adenoids are properly dealt with, and the question whether a remnant of tonsil is left behind or not is of relatively little moment. Indeed, it is often advisable to leave the tonsils alone; a complete adenoidectomy will often be followed by the desired results.

Mr. Jobson remarks: "The removal of a child's tonsils and adenoids in a minute or two by the guillotine is a much less spectacular operation than a set dissection lasting ten times as long." This statement may be a slip of the pen, for I cannot imagine how anyone can remove adenoids with a guillotine unless he uses the La Force instrument; dissection of adenoids would be equally impracticable. However effectively the tonsils are removed in children there is nothing "spectacular" about the operation unless adenoid tissue present in the nasopharynx is completely removed. I have dealt with a large number of cases in children where a perfect tonsillectomy has been performed but where apparently the adenoids have been neglected; the results are generally most disappointing. In my opinion the so-called recurrence of adenoids is a myth, and the explanation lies in the fact that, although much care has been taken to carry out a complete tonsillectomy, the adenoids have been dealt with in a perfunctory manner.

To remove all lymphoid tissue from the nasopharynx is not such an easy matter as is generally supposed—quite as difficult as tonsillectomy. It should be recognized that a sharp curette must be used not once but at least three times. If a small curette is employed the result is that the central portion of the adenoids is removed, leaving the lateral masses of lymphoid tissue in the region of the Eustachian tubes intact. In order to remove these lateral masses the curette is employed on either side. The ordinary curette is liable to leave behind lymphoid tissue situated immediately behind the septum. For removal of this tissue a special curette, which has a ring so small that it enters the upper and back part of the nose, is necessary. Such a curette I have employed for years.

If operators would use the term "adenoids and tonsils" instead of that usually employed it would help to concentrate attention on the really important part of the operation, at least so far as children are concerned.

My anaesthetist, Dr. H. W. Loftus Dale, would like to point out that since the introduction of vinyl ether (vinesthene) we have entirely abandoned ethyl chloride, and have been impressed by the absence of laryngeal or masseteric spasm and vomiting associated with this agent. For the past ten months we have used trichlorethylene for dissection of tonsils and removal of adenoids, and have been favourably impressed by the absence of congestion and any irritation to respiratory tract and diminished bleeding during the operation and the greatly diminished post-operative vomiting. In a very few adult cases a small amount of ether had to be used to obtain enough relaxation to insert the Boyle-Davis gag. In all cases, save in small children, endotracheal technique, with the usual precaution against aspiration of blood and debris, was adopted.—I am, etc.,

Aylesbury. NORMAN PATTERSON, F.R.C.S.

SIR,—Mr. T. B. Jobson is to be congratulated on his temerity in subscribing a discourse on the perennial subject of tonsillectomy, but its almost universal interest is, I think, sufficient justification for a periodical review.

Over the age of 15 or 16 the prevalent complication of peritonsillitis with subsequent fibrotic adhesion of the tonsillar capsule to the bed demands some form of dissection, but there is no valid reason why the guillotine operation should not be a success in practically all cases under this age. In my view the occasionally disappointing results of the guillotine operation can be traced to:

1. Inadequate illumination. There is no need to emphasize that the scientific technique demands a field of operation which is exposed to critical inspection at all stages. How often is this elementary requirement evident in some of the methods still employed to-day?

2. Rushed work. In my experience ethyl chloride anaesthesia alone, unless pushed to extremes, does not give sufficient time to allow for a neat removal of both tonsils and adenoid, particularly if a haemostatic type guillotine is used. A little supplemental ether well administered confers that invaluable extra two or three minutes and a most useful short period of amnesia, which excludes the "psychological trauma" recently discussed.

3. Inexperienced, incompetent, or frankly clumsy surgery. It is in the public interest that the future qualifying examinations should evolve some means of eliminating the ambitious but "ham-handed" potential surgeon, however exalted his theoretic and academic attainments.—I am, etc.,

Liverpool. JOHN ROBERTS.

Rehabilitation Centres

SIR,—The memorandum of the British Orthopaedic Association, as amplified by its president (Oct. 31, p. 526), places in excellent perspective the relative parts to be played by the rehabilitation departments of acute hospitals and by special rehabilitation centres—better called "rehabilitation continuation centres"—in the post-war world. But such a picture hardly fits the realities of the situation which confronts us to-day. In how many hospitals where fractures and other disabling injuries are treated is there anything approaching rehabilitation methods as now understood and practised? In the great majority there is either prolonged immobilization, or, at best, a perfunctory prescription of "massage and exercises," with no attempt to provide daily medical supervision of such remedial measures or to fill the patient's day with a programme of planned exercises, occupational therapy, and organized games all directed towards the prevention of the disability with which he is threatened. As a result, barely a week passes without the transfer to rehabilitation centres of the same dreary list of the products of excessive immobilization—stiff backs, painful wrists and shoulders, flexion deformity of knees; and that most ungainly progeny of fractured tibia out of persistent plaster—namely, "plaster equinus."

The danger inherent in the advocacy of separate rehabilitation centres at this present stage, apart from the undue drain on medical man-power, is the suggestion—implicit, if not actual—that such centres should relieve the hospitals of the essential task of setting up such an organization themselves and of starting the work of rehabilitation within a few days of a patient's injury or surgical operation. As to the bogy of hospitalization, nobody who has watched the changed outlook of orthopaedic patients in hospital after the introduction of a full programme of modern rehabilitation need have any fears on that score. It is not without significance that the E.M.S. has set up its own rehabilitation departments, not in isolated centres of post-hospital activity, but as an integral part of the fracture A departments and orthopaedic centres of the emergency hospitals themselves.—I am, etc.,

Pinderfields Emergency Hospital. HAROLD BALME.

Breast-feeding

SIR,—I have read with concern the letter of Dr. J. Gordon Mathias (Oct. 17, p. 465) regarding breast-feeding. It is such a dispassionate attitude of mind on the part of the family practitioner towards the subject that in many cases undermines the whole structure, both physical and psychological, upon which the success of breast-feeding is built.

I would recall the article by Prof. Charles McNeil (April 4, p. 429) in which he discusses the reasons why the infant mortality rate in this country compares unfavourably with a number of other countries. After reading his carefully considered conclusions one is left with the definite impression that this unfortunate state of affairs finds origin largely in the ignorance of the care of infants by many practitioners. How often during routine ante-natal examination is the question asked: "Do you intend to breast-feed this baby?" Does not this show a wrong mental attitude on the part of the practitioner, immediately conveying a sense of doubt to the mother, thus starting a trend which the practitioner, purely as the result of his dispassionate state of mind, is so often unable to stop.

My impression in this district is that breast-feeding has increased following a better understanding, which is largely the result of the national propaganda on the subject.—I am, etc.,

Tenterden. THOS. H. E. TAYOR-JONES.

•

SIR,—In a letter inspired by Prof. Charles McNeil's comprehensive article Dr. E. G. Housden (Oct. 10, p. 439) raises some interesting points. He says that the most difficult and dangerous period for mother and child in the effort to breast-feed is the four weeks succeeding the return from hospital or the departure of the doctor and/or midwife. With this none would disagree, but it is at this point that continuity of supervision is ensured by the arrival of the health visitor. She pays her first visit before the baby is two weeks old; she can revisit as often as may be necessary. If the mother is up and able to attend the clinic the health visitor may call between the weekly clinic visits if the mother is in difficulties.

While for the sake of order and coherence a clinic serving a large area prefers that patients should attend on the day for their own district, no anxious and harassed mother would be deterred from seeking advice if she reappeared before her visit was due. Although some mothers do come to the clinic to purchase artificial foods cheaply and to exchange chatty gossip, the aim of the clinic is child welfare, and we deplore Dr. Housden's impression that individual attention is impossible. The teaching and encouragement of breast-feeding are a most important aspect of infant welfare, and without individual attention carry little weight. The criterion of success is not number but the efficiency of the service rendered.

Even so all child welfare workers must be appalled by the small preparation of mothers who breast-feed their babies. When every factor has been considered and every aspect dealt with, the breast milk still diminishes. Almost all protest their willingness to breast-feed, but between desire and determination a great gulf seems to be fixed. Is the female physiological make-up changing, or are endocrine glands becoming less adequate, or should we reverse the "March of Time"?—I am, etc.,

Glasgow. MARGARET ISABEL MCGILL.

SIR,—Letters on this subject are making their appearance again, but surely the mortality rate, which few people seem to consider, is as worthy of consideration as the morbidity, which appears to be an obsession with most. Speaking of infantile diarrhoea, Holt says: "Of 1,943 fatal cases only 3% were breast-fed."—I am, etc.,

Wallington, Surrey. C. R. NUNAN.

"Constipation" in Breast-fed Babies

SIR,—Your correspondents might be interested in an article that was recently brought to my notice by Dr. S. K. Kon of the National Institute for Research in Dairying. It was published by F. W. Clements in the *Medical Journal of Australia* (Jan. 3, 1942, p. 12) and entitled "The Symptoms of Partial Vitamin B_1 Deficiency in Breast-fed Infants." He showed that partial vitamin B_1 deficiency in the food of breast-fed infants led to constipation, which could be cured by the administration of vitamin B_1 either to the infant or to the mother. Failure to gain in weight at a normal rate and vomiting were other symptoms of vitamin B_1 deficiency in breast-fed infants. The effect of administration by the mouth of 500 international units of synthetic vitamin B_1 per day was seen in a week and cure was generally effected within a fortnight. If this response was not obtained it was highly improbable that vitamin B_1 deficiency was the only cause of the symptoms. Dr. Margaret Price (*Journal*, 1940, **2**, 80) has also shown the beneficial effect of vitamin B_1 absorbate upon the weight and length of infants attending a welfare centre in this country.—I am, etc.,

London. W. C. W. NIXON.

Sedimentation Rate and the Sedimentin Index

SIR,—The letters following my paper on the sedimentation rate and the sedimentin index prompt me to reply to some of the points raised.

I wish to express my thanks to "Rural Practitioner" (Oct. 24, p. 497) for having put so aptly into words what I felt after reading the letters of Dr. P. W. Edwards and Mr. L. J. Cutbill and Dr. A. Clark-Penman (Sept. 26, p. 379). I should like to raise only one criticism. I do not think that a sedimentation rate carried out on the shaky floor of a moving car could be regarded the same as under "standard" conditions. It is true that we know very little about the laws governing the falling of particles in a standing or, alternatively moving environment; I have only observed the samples of blood conveyed after collection to the laboratory, and the bottles from the blood bank taken by car to the bedside of a patient who needs a transfusion in his home.

Dr. G. Day (Sept. 26, p. 379) seems to consider sedimentin as something contained in the plasma and to be looked upon as a constituent of it of the same rank as chlorides, sugar, calcium, etc. This is still to be proved; sedimentin may be a function correlated to the plasma and comparable to the complement or to the α and β isoagglutinins. Be it as it may, I think correction for anaemia to be essential, and am inclined to agree with Dr. Day's second hypothesis that the lowered cell volume is made good by replacement with whole plasma Cases of pernicious anaemia in relapse show an uncorrected sedimentin index well above 2.0 units, but falling within normal limits on correction; after a few weeks' treatment, when the blood count is normal also, the index is found normal. On the other hand, patients with fractures continue to present a very high sedimentation rate for long periods after the injury. I cannot also understand why Dr. Day considers that indices below 0.5 unit do not make sense; I have observed these more than once, usually in people with normal corpuscular volume who were investigated in the hospital for some condition eventually labelled "hysteria" or "anxiety neurosis." Such symptoms as the patients presented could not have been ascribed to lack of sedimentin.

As for the use of blood diluted with citrate solution, I feel that all estimations should be done on samples with as little interference or dilution as possible. If blood were diluted with citrate solution before estimating the urea or sugar, it would be necessary to correct for the dilution. Why treat the sedimentin differently? Also why does oxalated blood give figures 25% higher than citrated blood? If it is for the dilution 4 parts of blood to 1 part of citrate the figures ought to be 20% higher. If it is for-the-slowing down due to the sodium citrate the experiments of Ham and Curtis (*Medicine*, 1938, **17**, 447) show retardations of from 33 to 46%.

To conclude, I think that the comprehension of the nature of sedimentin would be facilitated by using a common and standard technique, no matter which technique be chosen; it seems to me obvious that the reading of the M.V. is the figure subject to least vagaries. If the haemoglobin instead of being referred to as percentage were reported in one case as grammes of haemoglobin and in another as mg. of iron per 100 c.cm. of blood, confusion would inevitably occur. This is now happening in the case of sedimentin and sedimentation rate. —I am, etc.,

Wolverhampton. B. L. DELLA VIDA.

SIR,—A more careful reading of our letters (Sept. 26, p. 379) would have saved "Rural Practitioner" (Oct. 24, p. 497) the trouble of refuting something we neither said nor implied. We are not averse from tedious and complicated tests providing the results are constant and reliable. Complexity is no absolute criterion of value. On experimental evidence alone we challenge the extravagant claims made for Day's sedimentin index as performed by "Rural Practitioner," who appears to be a close collaborator if not a near blood relation of Dr. Day.

The inconstant effect of temperature on the E.S.R. is shown by these few examples drawn from a large number of duplicate experiments:

Case	M.V. at 65° F.	M.V.	Temperature
(1) E. N.	92	116	53° F.
(2) D. T.	46	32	50° F.
(3) S. T.	10	4·5	50° F.
(4) J. B.	84·5	75	50° F.

Reduction of temperature of the test usually results in the slowing of the E.S.R., but occasionally in rapidly sedimenting bloods the reverse occurs, so one of these has been included in the examples. The discrepancies are not constant, and in No. 3 it is over 50%.

This ignoring of temperature and also perpendicularity of the column of blood when carried out in a motor car—only two of many variable factors influencing E.S.R.—indicates the value which can be put on the small fluctuations of the sedimentin index claimed to be so significant by Dr. Day and/or "Rural Practitioner." Given a standard technique, reliable and consistent results can be obtained by almost any method of estimating E.S.R. The Westergren remains after over 20 years as good as any method and better and simpler than some.

Our protest still stands against the over-elaboration of a useful test and the fallacious and unscientific appraisal of clinical changes on variations considerably less than the experimental error of the method employed.—We are, etc.,

PETER W. EDWARDS.
A. CLARK PENMAN.
Cheshire Joint Sanatorium, Market Drayton. LESLIE J. CUTBILL.

Splenectomy in Purpura Haemorrhagica

SIR,—I was very interested in the discussion on splenectomy in purpura haemorrhagica, and ask for permission to add something to it. I believe I have had the longest experience of this operation, and, like a mother naturally follows the ways of her child, I watched its development especially closely since my first cases in Prague. I saw two of the three cases described in my first papers for the last time shortly before I had to leave Prague into exile 3½ years ago, and the third one some years before that. They were all completely free from symptoms and signs of the disease which they had suffered from for many years and which had brought them into constant danger to life. The literature is very great, mostly in America. Dr. Bruce Williamson (Oct. 3, p. 407), who changed his original opinion so profoundly, will not easily find a companion, although there are similar voices (perhaps not quite so definite). The essence of all experience laid down in the medical literature of the whole world is, as Prof. L. J. Witts writes (Oct. 17, p. 466), that the value of splenectomy in purpura haemorrhagica is now a matter of orthodox therapeutics, with *one* condition: that the diagnosis is established beyond doubt by a competent haematologist. And this condition I believe is certainly easily fulfilled in your country.—I am, etc.,

Halifax General Hospital. PAUL KAZNELSON.

The Future of the Profession

SIR,—I belong to that large group of doctors who think it matters little whether the profession becomes a State service or not. What does matter is whether doctors are to be provided with such conditions of life and work that honest and good medical work can be done, and an efficient comprehensive service provided for the community.

It seems to be generally agreed: (1) that present conditions and the present services are defective; (2) that some changes are required; and (3) that those changes should be either towards a State service or towards a radical modification of the existing services. Accepting whole-heartedly the need for change, I think the root problem involved in choosing between the proposed alternatives is bound up in the word "planning."

1. What do we mean when we use that word? Do we mean a rigidly structured professional society in which every individual is given (by authority, I suppose) his exact place and prescribed function? Or do we mean what the biologists would call a patterned professional society? The difference of aim involved in the words "plan" and "pattern" is vital to every organized democracy. In a planned State service a formal rigidity must tend to destroy initiative; in a patterned State service the required regularity and discipline must be attained and preserved. I implore all doctors to consider once again whether their thinking is governed by a philosophy suitable for chemical atoms or by a biological philosophy suitable to human beings (Haldane, J. S., *Philosophical Basis of Biology*).

2. My second question is, What do we mean when we argue about the importance of the right to choose doctor or patient? Who cares what patients are allocated to him provided he can get rid of those he cannot succeed in treating? Who cares what doctor he is sent to provided he can make a change if need arises? Let us keep the real point clearly before us. It is the "right to change," not the "right to choose." Free movement of units is always possible in a patterned society, never in a planned one (*vide* wartime industrial and professional life).

3. We should ask how we can avoid the real dangers of making medicine an "established profession" in which a sterile orthodoxy stifles initiative. Shall we have room within our new services for the really unorthodox doctor? If not, a new "medical Luther" will soon arise, and side by side with "established medicine" will grow up a protestant and nonconformist medicine! If our planners hate vested interests, let them take heed lest they create them. Once again, the root problem is philosophical, of that I am persuaded.

Lastly, we are told (*a*) that the reform of the profession is urgent and should be dealt with now, and (*b*) that no significant change can take place for a long time, and anyhow nothing should be done until the end of the war. Surely the great question should be, What can we personally do, first, to resist static planning, and, secondly, to promote a true patterning of the profession?—I am, etc.,

Worcester HOWARD E. COLLIER

Safe Milk

SIR,—Your advocacy of pasteurization is well known, so it is a pity that little appears in the *Journal* about the progress made towards a better solution of the problem of safe milk.

Your leader on bovine tuberculosis (Sept. 26, p. 571) gives very little idea of the range of the discussion on the control of cattle disease reported in the *Proceedings of the Royal Society of Medicine* (May, 1942). From what was said during the discussion it is quite evident that the eradication of bovine tuberculosis in this country is within our reach. In the United States, Mr. H. T. Mathews said, twenty-five years' efforts have reduced the incidence from an average of 5% to 0.5%. The steps he advocated—extension of the Attested Herds Scheme, calf nurseries, and vaccination—only need to be pressed forward to be successful. Prof. Dalling's use of Wells's vole bacillus in the vaccination of calves seems to show that this will give a better immunity than B.C.G. vaccine.

As to distribution of milk, pasteurization as a means of preserving milk is out of date. Chilling, from the moment the milk leaves the cooler until it reaches the domestic refrigerator (which must no longer be looked on as a luxury), is the method that will come.

It is up to us to encourage these steps rather than to sit back and contentedly advise pasteurization because it has the merit of being easy, while to free the country's herds of tuberculosis will be arduous at first and will call for constant encouragement from those who should know what is right.—I am, etc.,

WILLIAM PICTON.

Cost of Treatment for Tuberculosis

SIR,—I have read the report of the M.R.C. Committee on Tuberculosis in Wartime, and note with pleasure the recommendation that the dependants of tuberculous persons should be given substantial financial help during the period of treatment. From the statement recently made by the Minister of Health in the House of Commons and later on the wireless, it appears that this principle has been accepted by the Government. Is it, however, realized that in many parts of the country, far from financial help being provided, the treatment of the tuberculous patients themselves is not free, and that they are actually assessed on their alleged ability to pay for their stay in a sanatorium?—I am, etc.,

F. D. G. THOMAS,
London, N.20. Assistant Tuberculosis Officer.

Obituary

ROBERT ESMOND MOYES, M.D.

Dr. R. E. Moyes, who died on Oct. 23, aged 58, had been secretary of the North Northumberland Division of the B.M.A. for eleven years and its chairman in 1932-3, and president of the North of England Branch in 1938-9. He was elected chairman of the Northumberland Insurance Committee in 1937. A colleague writes:

The sudden and unexpected death of Robert Esmond Moyes has stunned a wide circle of friends, both within and without the profession. In all the circumstances of life, both grave and gay, Moyes was an ideal support and companion. Broad-shouldered and broad-minded, he carried the burden of a busy life and practice with a sympathetic sanity.

At Edinburgh University, where he graduated in 1905, he had worked hard and had a host of friends. His father died while he was still a student, and force of circumstances compelled him to go into practice immediately after qualification, and he had to forgo the boon of holding resident appointments. The sacrifices made by his widowed mother before his qualification were ever in his mind, and no son could have done more to give her comfort and support as soon as he found himself in a position to do so. Settling in the colliery village of Broomhill, the practice included patients in the colliery itself and in the surrounding country. Moyes soon made a reputation as a most reliable practitioner. Happily married in 1915, he had scarcely settled in practice when the war called him to the R.A.M.C. and for two years he served in the East. Returning to Broomhill, his practice steadily increased, and there he lived and worked until, some years ago, he moved his home to Warkworth, leaving an assistant in the Broomhill house and surgery. Throughout his 37 years in Broomhill and Warkworth Moyes did a stupendous amount of work both day and night. Starting his round at 8.30 a.m., his widespread practice might have fully occupied his time, but in spite of the daily routine he found time to do much work on committees both of the British Medical Association and of the Northumberland Insurance Committee.

Throughout the years Moyes did his utmost to keep himself up to date in all branches of medicine. No doctor living at a distance from Newcastle was ever a more constant attender at postgraduate classes and medical society meetings, and he served a year of office as president of the Northumberland and Durham Medical Society. His large practice in colliery and rural areas comprised patients drawn from every grade of society. In pit cottage, farmhouse, and country house it was always the same Moyes. The patient had been thoroughly examined and assiduously attended; and when he called for help the consultation was invariably of his own seeking. There was always the beneficent atmosphere of confidence only met with in the practice of a really good doctor.

Moyes was a sportsman in the true sense of the word, and though the exigencies of his practice curtailed his opportunities, it enhanced the pleasure of both the sport and the companionship. An ideal companion on the golf course, an unselfish shot, and a painstaking fisherman, Moyes was certain of friends and endless opportunities of indulging in the many sports at which he excelled. Having played football for Edinburgh University, he always had an intense interest in the game, and seldom missed the Internationals at Murrayfield. Twice a year a company of friends composed of consultants and general practitioners (the Dormy Club) used to spend a week-end at Silloth for golf. Moyes thoroughly enjoyed these days of complete relaxation; and all enjoyed Moyes, who was sure to have some anecdote, usually some droll episode in his practice, true and humorous, and often told at his own expense.

Having the confidence of his fellow practitioners, it was inevitable that great calls should be made upon his time to serve on committees, and he was an ideal member and chairman of any committee on which he served. He had a natural and spontaneous tact which implies self-restraint, good temper, and quick and kindly sympathy with the feelings and opinions of others. He always seemed to gain his point, yet he never appeared to be in antagonism with anyone. Since 1939 Moyes had enormously added to his already burdensome practice and commitments by doing the work of colleagues in the district who had been called to the Services. During the last two years he had had no time to relax, and it is pretty certain that these strenuous years contributed to his early death.

PROF. HEDLEY WRIGHT, M.D.

Prof. G. S. WILSON sends the following at our request:

The brief obituary notice of Prof. Hedley Wright that appeared in the *Journal* on Sept. 26 needs amplification if due tribute is to be paid to one who occupied a leading position in the ranks of British bacteriologists.

Wright's early work at Edinburgh was concerned largely with serological problems, particularly in relation to the diagnosis of syphilis. During his seven years at University College Hospital, 1923-30, he concentrated his attention on infection and immunity. His careful qualitative observations on the mode of reaction of the rabbit to experimental pneumococcal infection added materially to our knowledge of the clearing mechanism of the normal and vaccinated animal. Two smaller contributions during this period were of importance in starting lines of investigation that were followed up by later workers. A study of two cases of puerperal fever due to pneumococci led him to conclude that infection might be conveyed to the patient from attendants or other persons in the environment; and the demonstration of bacteriaemia within a few minutes of urethral operations paved the way for the observations of Okell and Elliott on the streptococcal invasion of the blood stream following the extraction of septic teeth. From 1930 to 1934, while at Sydney, he interested himself in nutrient media. His finding of bacteriostatic substances in peptone that could be rendered inactive by reduction enabled him to devise a simple method for the preparation of basal media which is now extensively used.

The last eight years of his life, spent at Liverpool, were devoted to the application of bacteriology to public health problems. His work on the laboratory diagnosis of enteric fever did much to improve the current methods and to reform our ideas on the frequency of paratyphoid bacilli in the faeces during the early stages of the disease. His chief interest, however, lay in diphtheria. Taking full advantage of the opportunity that Liverpool afforded him, he studied this disease from different angles, and by a happy combination of bacteriological, epidemiological, and statistical methods, which served as a model for other investigators to copy, he reached conclusions of both laboratory and administrative significance. The whole of Wright's work was characterized by an insight, thoroughness, and accuracy that will remain the inspiration of all who knew him.

WILLIAM FRETSON SKINNER, aged 60, died at Sheffield on Sept. 30. He was the third generation in the practice. His grandfather, William, lectured on anatomy in the Medical School in 1852, and his father also taught anatomy. Educated at Wesley College and University College, Sheffield, with a brief spell in London at U.C.H., he qualified, and after holding a resident post at Chesterfield and a country assistantship he joined his father in a large industrial practice. It soon became too big for him and he took a partner. The partner joined up on the declaration of war, and Skinner was left to work a huge practice scattered to the four quarters of the city by slum clearance and bombing. Last winter he got a thrombosis in a tibial artery but continued work until it was followed by a coronary thrombosis, from which he died. To this bald account one must add an appreciation of a really remarkable man. One of those men who read little but learn much from experience, he was intensely practical and, I believe, never neglected to make a thorough examination. Possessed of a keen eye and a really uncanny intuition for prognosis, he became an extraordinarily good doctor. He was one of the kindest men, perhaps the kindest, I have ever met. He thoroughly enjoyed his work of visiting the sick and would do anything to help them. There are many anecdotes about this aspect of his character. He seemed to understand his patients and their relatives, and indeed to know the whole family by their christian names and possess their confidence. His shrewdness, powers of observation, sense of humour, and kindliness made it a joy to meet him in consultation. May the profession long continue to possess such members.—A. E. B.

Dr. **Herbert George Harris**, who had practised for the last 35 years in Southampton, died at Ashurst in the New Forest on Oct. 3 at the age of 68. For 20 years he was medical officer to the Ordnance Survey Office, and among other appointments he held was that of honorary medical officer to the Hampshire Girls Orphanage. He was educated at Bradfield College and studied medicine at St. Bartholomew's Hospital and Durham University, where he graduated M.B., B.S. in 1898 and M.D. in 1901. At the funeral service his friend Canon R. B. Jolly spoke of the loss which people felt at the passing of a beloved physician, a doctor whom his patients also regarded as their friend. Dr. Harris was the only son of the late Dr. William John Harris of Worthing.

Dr. **Frank Robinson**, who retired in 1935 from the post of medical officer of health and school medical officer for Cambridgeshire after 26 years' service, died suddenly on Oct. 5. He studied medicine in Manchester and graduated M.B., Ch.B. of Victoria University in 1891, proceeding M.D. in 1895 with a thesis on the clinical features of small-pox, and taking the D.P.H. of the English Royal Colleges in 1901. In 1905-9 he was assistant M.O.H. under the West Riding County Council. During his long period of work for the Cambs. County Council Dr. Robinson lectured on sanitary law and administration to candidates for the D.P.H. of the University. He was a Fellow of the Society of Medical Officers of Health and of the Royal Sanitary Institute. He joined the B.M.A. in 1910 and was president of the Cambs. and Hunts. Branch in 1933-4; since 1938 he had been emergency officer for the two counties and held the post of hon. secretary of the local medical war committee. R. F. writes: The tragically sudden death of Frank Robinson came as a great shock to his many friends. Before his arrival in Cambridge he had acted as medical officer in one of the Liverpool Poor Law Institutions, where he had had extensive experience of both small-pox and typhus fever, two diseases in which he was an acknowledged expert. Just before his death he had been appointed by the Ministry of Health as a consultant for the diagnosis of the latter disease in doubtful cases. During his long period of office under the Cambridgeshire County Council he saw many changes in the public health services. Naturally he had to administer many new developments in the work, and at the end he left a smoothly working service which presented his successor with few difficulties. In his retirement he received many tributes of respect and affection. Though a full-time officer he was, at any rate latterly, a firm believer in the voluntary principle, and many were the voluntary bodies on which he served, either as the representative of the County Council or as a directly elected member, but his interests extended far beyond his daily work. The theme of his life was service, particularly perhaps the service of youth, and no appeal to his generosity went unsatisfied.

The death of Major D. Y. **Richardson**, R.A.M.C., at the early age of 36, writes a colleague, came as a profound shock to his many friends. Douglas Richardson came to Lincoln in 1934, taking up a partnership in general practice. However, his main interest was in ear, nose, and throat work, and he later took the London diploma in oto-laryngology. Skill in his specialty, coupled with a keen and kindly interest in his patients, led to a rapid increase in consulting work and to appointments at the Lincoln County Hospital and the E.M.S. Hospital at Louth. Volunteering for the Services he entered the R.A.M.C., and was attached to a military hospital as ear, nose, and throat specialist at the time of his death. Conscientiousness in his work and the sincerity of his character, added to great personal charm, made Douglas Richardson very popular with patients and colleagues alike; and they, with a wide circle of friends, will mourn his loss and extend their heartfelt sympathy to his widow and four children.

Universities and Colleges

ROYAL COLLEGE OF PHYSICIANS OF LONDON

At a quarterly Comitia on Oct. 29, with Sir Charles Wilson, President, in the chair, Prof. W. G. Barnard, Major-General A. G. Biggam, Dr. Geoffrey Evans, Sir William Fletcher Shaw, and Sir John Stopford were elected Councillors. Dr. A. E. Clark-Kennedy was re-elected a representative on the committee of management of the Conjoint Board, and Sir Comyns Berkeley a representative on the council of the Central Midwives Board.

The President nominated Dr. W. E. Hume as Harveian Orator and Dr. J. W. Brown as Bradshaw Lecturer, both for 1943, and announced the appointment of Dr. A. H. Gale as Milroy Lecturer for 1944, the award of the Streatfeild Scholarship to Miss Enid E Sampson, the Jenks Memorial Scholarship to A. J. Graham, and the Linacre Scholarship to C. R. Cheadle.

The following, having satisfied the Censors' Board, were admitted Members:

M. G. C Ashby, B.M.Oxon., N. D Compston, M B.Camb., W. H Hargreaves, L.R C P., E. J. C. Kendall, M.B.Camb., L. Nagley, M D Leeds, J. Ll. Penistan, M.B Lond., E. Petrie, M B Lond., J. S. Pippard, M B Camb., R E. Rewell, M B.Lond., J. F Smith, M B Camb., L. W. Smith, M B.Camb., R. B. Thompson, M.B.Durham, A Topping, M.D.Aberd.

Licences to practise were conferred upon the following 274 candidates (including 28 women) who have passed the final examination of the Conjoint Board and have complied with the by-laws:

Patricia R. M. Adlington, J. N Agate, P L Allen, E Asquith, E. O Barnes, A G. Barnsley, H. W. A. Baron, T. T. Bartlett, R W. Bazeley, Ruth A Bell, C. P. Bennett, H H. Bentall, C. Ben-Yallouz, G G B Blackman, J J. Bligh, S. O. Boldy, P B Booth, R. J. Bower, R. A Bradford, P. W. Brand, K. Braun, A H W Brenan, R. N Briggs, Ruth M Burt, P. H Buxton, N A. Campbell, A. W. Capon, R J D. Carrick, L S Castleden, Marjorie E. Chaplin, D P. Choyce, Ann B. Clark, M W. L. Clements, P Coggin Brown, J. A. H. Collyns, D. J Conway, E G Cook, J. B Cook, Rosemary I Cook, J. A. L. Cooper, P F Cooper, Prudence A. Cooper, M G. Corcos, J M G. Costello, Elizabeth Cullis, C. F A. Cummins, Joan M. Daniel, O Daniel, A S Davidson, D. P. Davis, H. Davis, W E. Denbow, R. J. Dickson, Ll S. P. Divers, C. E. P. Downes, J. T. Doyle, J G. Dumoulin, M P. Durham, V. Edmunds, H. W Eldridge, C. J L. Elsdon, R. N M Eminson, J D. Everall, G. E. Fearn, P. D. Fergusson, M Fertig, R J. Forster, G. C. Foster-Smith, M B. Fox, J. A Frais, B L. Frank, P Fry, D. I Fullerton, J O. Gallimore, M. Gamal el-Din, C. D. Garratt, G. E Garratt, K O. George, D Gill, A. E. Ginn, J F. Goodwin, J. V. T Gostling, S Gottlieb, A. J. R Green, K. Greenwood, J. S. Grewal, D. J. Hadfield, R G H Hall, A. H Hamed, S F Hans, D. M. Hare, A J M. Hargreaves, J R Harries, W A. Harries, R. M. Harrison, W. H. Helm, Frieda R Hendeles, J C Hesketh, S R Hewitt, A. C. Hicks, T. S. Hindle, F Hoffstein, Betty Holden, E. Holden, P. Holliday, S. C. H Hood, P. H. S. Hooper, H. Horbacz, A. L. Horetzky, H. J. Houghton, Geraldine M. Howard, S. H. F Howard, D A. Howell, T. E. Hughes, R. B. Illing, K P Isserlis, P. S Jaikaran, W James, R T. Jenkins, W R. John, P. F. Johnson, H. R Jolly, O M. Jonathan, A E. Jones, D. V. M. Jones, W. B E Jones, D. Keidan, T. D Kellock, R W. Kind, L. G. Kingdom, T G. Kletz, M. A. Kumar, P Lambah, V. H. Lees, M E. Lemerle, S G. F. Winocour, R. Winston, J. F. R Withycombe, C. R Wood, L. P. J. Wright.

Diplomas in Public Health were granted, jointly with the Royal College of Surgeons, to Gwendolen M. Allen-Williams, Nora E. R Archer, Hilda M. Robertshaw, F. S. D. Thompson, H G. Topping Diplomas in Child Health were granted, jointly with the Royal College of Surgeons, to the 9 candidates whose names were printed in the report published on Oct. 24 (p. 499).

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

At the annual meeting of the Faculty the following officers were elected for the ensuing year: *President*, Mr. James H MacDonald: *Visitor*, Mr. William A. Sewell; *Honorary Treasurer*, Mr. William J Richard; *Honorary Librarian*, Dr. W. R. Snodgrass; *Representative on General Medical Council*, Mr. Andrew Allison.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

A quarterly meeting of the Council was held on Oct. 24, with the President, Sir William Fletcher Shaw, in the chair.

The following were admitted: *To the Fellowship:* W J. H M. Beattie, C. M. Gwillim. *To the Membership:* Muriel Boycott, J. W. D Buttery, Marie H. Calverley, I MacG Jackson, Mary K Lawlor, W. J. McCord, Eleanor M. Mills, Mary R. Thompson, H. M. Wolff *In absentia,* H Agar, T. A Gillie, J. F. B Wyper.

The following have satisfied the examiners and have been awarded the Diploma of the College: I C Barne, Margaret R. Biggs, Ruth C. M Brown, Gertrude M Child, Edith M Druitt, Margaret D Dudley-Brown, Anne C Fletcher, F. G. M. Fraser, Mairidh A. M N. Graham, Margaret A. Hay, J. Hesketh, Eluned M. Lloyd-Davies, R. A Manclark, G, H Moore, J. E. E. Morgan, H A. Ripman, E Sharp, Daisy M Smith, Ruth M Stubbs.

The Services

The King has approved the award of the R.N.V.R. Officers' Decoration to Surg. Cmdrs. A. W. Kendall, R. R. B. Roberts, and H. Winstanley, R.N.V.R.

CASUALTIES IN THE MEDICAL SERVICES

War Subs. Capt. SAMUEL HENRY SEGERMAN, R.A.M.C., who is included as "killed" in an Army Council Casualty List published on Oct. 31, was born on March 3, 1914, and was educated at the University of Leeds, where he graduated M.B., Ch.B. in 1938. He also took the D.T.M. of Liverpool in the same year. Before entering the R.A.M.C. as temp. lieut. in Dec., 1940, he was in practice at Middlesbrough and Leeds. He saw service in the Middle East.

Wounded.—Capt. G. M. Calder, R.A.M.C.

Prisoners of War.—War Subs. Capt. H. Bloom, R A.M.C., War Subs. Capt. W. E. G. Bradford, R A.M.C., Lieut.-Col. W. B. F. Brennan, R.A.M.C., Capt. L. B. Gunn, R.A M.C., Capt. P. L. Headon, R.A.M.C., Capt. L. V. Macdonald, R.A.M.C., Prob. Temp. Surg. Lieut. J. C. de R. Sugars, R.N.V.R., Surg Cmdr. V. F. Walsh, R.N.

Missing, Believed Prisoner of War.—Major T. F. O'Donnell, I.M.S.

Missing, Probably Prisoner of War.—Major K. F. Alford, I.M.S.

Missing.—Capt. R. W. Lennon, R.A.M C.

DEATHS IN THE SERVICES

Surg. Rear-Admiral ALEXANDER JOHN JAMES JOHNSTON, R.N. (ret.), died at Crapstone, Devon, on Oct. 17, aged 87. He received his professional education at Guy's Hospital and qualified M.R.C.S.Eng. in 1877 and took the L.R.C.P.Ed. in the following year. Entering the Royal Navy soon afterwards he became deputy surg.-general (now surg. rear-admiral) in 1912, and retired after the war of 1914-18. During the latter part of his career he held the posts of deputy surg.-general of the Royal Naval Hospital, Malta, and surg.-general of the Naval Hospital, Chatham, and, later, was a temp. lieut.-col. in the R.A.M.C. He served throughout the war of 1914-18, receiving the medals. He joined the B.M.A. in 1899, and when the Association met at Leicester in 1905 he was vice-president of the Navy, Army, and Ambulance Section.

Lieut.-Col. CHARLES HARDWICK LOUW MEYER, I.M.S. (ret.), died at Exeter on Aug. 30, aged 82. He was born at Grahamstown, South Africa, on Nov. 19, 1859, the son of Capt. Nicholas Meyer, an officer of the old Prussian Army, before the German Empire came into being, who came to England, was naturalized, and entered the British service. Lieut.-Col. Meyer was educated at Grahamstown, Queenstown, and Bloemfontein, and at Guy's Hospital, qualifying M.R.C.S. in 1883. In the same year he graduated M.B. (with honours in forensic medicine), B.S. (with first-class honours) of the University of London, proceeding M.D. in 1885. After filling the posts of house-surgeon and obstetric resident at Guy's he entered the I.M.S. as surgeon in 1887, gaining first place in competitive examination in Feb. and first place in examination at the Army Medical School, Netley, in July, and winning the Herbert Prize and the Ranald Martin Memorial gold medal. He became lieut.-col. after twenty years' service and retired in 1913. Most of his service in India was spent in Bombay, where in 1889 he was appointed professor of physiology, histology, and hygiene in the Grant Medical College (later becoming principal), and physician and registrar of the Sir J. J. Hospital, and professor of pathology in 1902, holding these posts until his retirement. He rejoined for service in the war of 1914–18, when he was second-in-command of the Lady Hardinge Hospital for Indian Troops at Brockenhurst in 1914–16, consulting physician to the Waziristan Field Force in 1917 and to the war hospitals of the Southern Army in India in 1917–19, and was mentioned in dispatches in 1918. After retirement he was consulting physician to the Osborne Convalescent Home and a member of the India Office Medical Board in 1921. He had been a member of the B.M.A for 50 years and served on the Central Council in 1913–14.

Medical News

The Annual Meeting of Fellows and Members of the Royal College of Surgeons of England will be held at the College in Lincoln's Inn Fields, on Thursday, Nov. 19, at 2.30 p.m., when the President hopes there will be a good attendance.

Prof. J. C. Drummond, D Sc, scientific adviser to the Ministry of Food, will deliver a series of lectures on "The History of Our More Important Foods" at the Royal Institution, 21, Albemarle Street. W., on Tuesdays, Nov. 24, and Dec. 1, 8, and 15, at 3 p.m.

The Benjamin Ward Richardson Lecture will be delivered at the Royal Sanitary Institute, 90, Buckingham Palace Road, S.W., on Wednesday, Nov. 25, at 2.30 p.m., by Lieut.-Col. D. J. Anthony, M.R.C.V.S, on "The State of Meat Inspection in Britain at War."

A general meeting of the Tuberculosis Association will be held at 26, Portland Place, W., on Friday, Nov. 20, at 2.45 p.m., when there will be a discussion on "The Treatment of Tuberculous Pyothorax," to be opened by Dr. J. Clifford Hoyle, Dr. W. C Fowler, and Mr. R. C. Brock.

Under the auspices of the British Council a reception was held in Liverpool on Nov. 6 by the Vice-Chancellor of the University and Sir Robert Kelly, F.R.C.S, at which members of the local medical profession and medical representatives of the Allied Nations heard an address by Prof. Henry Cohen, M D., on "The Principles of Diagnosis: A Retrospect and a Prospect."

At the inaugural luncheon at the Mansion House Mr. Herbert Morrison, Home Secretary, described as a wise and rational step the amalgamation of the Queen's Hospital for Children and the Princess Elizabeth of York Hospital for Children, which will function in future as the Queen Elizabeth Hospital for Children. He said it was true that a substantial portion of the London voluntary hospitals were large and efficient, but a number of them were small and uneconomical and their efficiency open to question. He hoped that King Edward's Hospital Fund for London would help to bring about further amalgamations, and advised greater co-operation in the purchase of supplies. He thought it was a good thing that there should be a certain degree of competition and rivalry in enterprise between municipal and voluntary hospitals.

The Joint Committee for Soviet Aid is launching a nation-wide appeal for medical aid for the soldiers of the Red Army. Every kind of medical supply, equipment, and comfort is urgently required in ever-increasing quantities by the Red Army and the Soviet people in the fighting zones. Donations may be sent to Sir Peter Chalmers Mitchell, F.R.S., Hon. Treasurer, Joint Committee for Soviet Aid, 171, St. Stephen's House, Westminster, S.W.1.

The Ministry of Health, with the co-operation of the Ministry of Information, is launching another winter health campaign to renew the attack on the careless cough and sneeze by means of persistent education on the dangers of droplet infection. Publicity media will be posters, exhibitions, films, and broadcasts.

On Nov. 3 the Minister of Health performed the opening ceremony of the 600-bed Merriston Hospital, near Swansea, which has been built at a cost of £180,000 under the Emergency Hospital Scheme. Until heavier emergency demands arise, five wards, with 200 beds, are being placed at the disposal of the Welsh National Memorial Association for cases of tuberculosis, and the hospital will also be used to relieve the pressure on the Swansea and General Eye Hospital.

At the time of the British occupation of Eritrea the Eritrean section of the Italian Society of Medicine and Tropical Medicine had ceased to function. In order to restore to normality the medical services, and in the interests of co-operation between Italian and British medical men, it was thought to be essential that this society should reopen its meetings and activities. We have received from Lieut.-Col. R. H. Bland, R.A.M.C., principal medical officer for Eritrea, the first two numbers of the *Bolettino* published at Asmara under the editorial direction of Prof. Giovanni Ferro-Luzzi. It is a substantial magazine, each number containing well over 100 pages printed in Italian.

Olive oil is supplied only against a doctor's prescription, but even so there is no guarantee that it will always be available, and the Ministry of Food announces that arachis oil may be substituted provided the prescriber's consent is first obtained. Arachis oil has already been used as substitute in many *B.P.* and *B.P.C.* preparations.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week there was a general rise in the incidence of infectious diseases. The largest increases were those of measles 1,007 cases, whooping-cough 77, and acute pneumonia 51. Scarlet fever, with 84 fewer cases than last week, was the only disease for which a fall in incidence was recorded.

Within the counties no very striking fluctuations occurred in the trend of scarlet fever, diphtheria, and whooping-cough. The largest variation was that of Yorks West Riding, where the numbers of cases of scarlet fever and whooping-cough were 61 and 43 respectively below the totals of the preceding week.

There was a rise of 12 cases in the incidence of dysentery: 30 cases were reported in London, the largest total since February; 10 occurred in Woolwich: and the remaining 20 were distributed over twelve boroughs. Other large county totals were Yorks North Riding 31 (Middlesbrough C.B. 29); Yorks West Riding 29 (Leeds C.B. 15, Sheffield C.B. 8); Derbyshire 12 (Derby C.B. 7, Shardlow R.D. 5); Southampton 10 (Droxford R.D. 7); Wales 24 (Cardiff C.B. 9).

In *Scotland* there was a further rise in the incidence of diphtheria and measles of 39 and 26 cases respectively. Of the 257 notifications of diphtheria, 93 were reported from Glasgow; and of the 379 cases of measles, 120 were notified in Paisley burgh.

In *Eire* the incidence of acute poliomyelitis remains at a high level. The 28 cases were distributed through ten areas. The most important centres of infection were the rural district of Co. Roscommon 8 cases, and Co. Clare, Ennis U.D. 5 cases. One case of typhus was reported from the rural district of Co. Galway.

Small-pox

Six further cases of small-pox have occurred in Edinburgh, bringing the total up to 8; all are in males, and all, as well as the suspected cases, are connected with the original outbreak. The medical officer of health in a statement to an emergency meeting of the Public Health Committee said that the cause of the outbreak was at present unknown. No evidence had been found that could link these cases with the outbreak in either Fife or Glasgow. It was possible that a visitor to the institution had been responsible for introducing the infection.

Small-pox in Fife County

The following letter has been received:

"SIR,—I refer to the statement in the *Journal* of Nov. 7 (p. 565) regarding the Fife County small-pox outbreak. The statement, which appears to be founded on Press reports, is liable to give rise to misunderstanding. No contacts were allowed to return to work. They were not only isolated and kept under medical supervision but received the unusual advantage of being paid allowances. The reference to a colliery strike was an exaggeration. A girl who was not a contact was seen at a pit-head bath to have a rash on her back. Her companions became agitated, but were quickly reassured by an officer of the Public Health Department, and the incident closed.

"The outbreak was completely under control from Oct. 6, when the Public Health Department made the diagnosis, and all restrictions were removed on Nov. 3. In all, there were 27 patients with small-pox, 7 of whom died.—I am, etc., G. MATTHEW FYFE."

Measles

The incidence of measles has increased for six consecutive weeks and is now a little more than two and a half times the level at the beginning of this period. The largest increases in the week under review were those of Lancashire 226, Yorks West Riding 153, Leicestershire 106, Derbyshire 104. The rate of increase has been much greater in the North than in the South during recent weeks. The change in the geographical distribution of measles that has resulted can be illustrated by comparing the percentage distribution with that of the week ending July 25, when the total notifications were approximately the same.

Division	Week ended July 25 : 6,817 Notifications	Week ended Oct. 24 : 6,803 Notifications
London	10·2	5·3
South-Eastern	14·7	4·2
South-Western	0·9	0·8
South Midlands	8·8	4·4
Eastern	7·3	3·7
West Midlands	6·1	6·6
North Midlands	6·3	10·4
North-Western	23·3	24·4
Yorkshire	10·3	28·2
Northern	9·1	8·3
Wales	2·9	3·7

Returns for the Week Ending October 31

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 2,583, whooping-cough 1,015, diphtheria 898, measles 6,812, acute pneumonia 583, cerebrospinal fever 57, acute poliomyelitis 27, dysentery 290, paratyphoid 7, typhoid 12.

No. 42

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Oct. 24.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1942					1941 (Corresponding Week)				
	(a)	(b)	(c)	(d)	(e)	(a)	(b)	(c)	(d)	(e)
Cerebrospinal fever ..	66	5	21	—	6	107	7	32	2	8
Deaths		—	—				—	1

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE No.—B.M A. and *B M J.*: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent, London;* SECRETARY, *Medisecra Westcent, London.*

B M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Anaemia in Young Adults—Dietetic?

Dr. M. E. LAMPARD writes: In reply to Dr. G. D. Summers (Nov. 7, p. 566) parsley is a very rich source of vitamin C.

Aspirin for Asthma

J K. D. writes: The notes that have appeared in the *Journal* on the subject of the value of aspirin in asthma prompt me to record my own personal experience. Twenty-two years ago, after I had suffered from asthma off and on for 28 years—i.e., from early boyhood—I made the discovery of aspirin as a preventive in my case. My attacks were almost invariably nocturnal. During a spell of frequent attacks, when 4 a.m. never passed without my being awakened by an attack, I had a headache one evening. At bedtime I took an aspirin tablet, 5 grains, for the headache, and to my surprise I was relieved not only of the headache but for the night of asthma also. A few nights' trial with and without aspirin proved that the relief was no mere coincidence, and that my asthmatic tendency was very much reduced by one aspirin tablet. I therefore continued to take one aspirin tablet every night for some years, and I was very seldom troubled by more than slight symptoms. For the last 15 years, although I am still at times conscious of the tendency, I have regarded myself as practically cured. There may have been other factors partly responsible for my relief. I think there have been—e g., aborting any threat of an attack by a small dose, about four minims, of adrenaline hypodermically—but I am convinced that my small dose of aspirin has been of the greatest value. I never took more than one tablet. I have known a few patients who got some relief from aspirin, but in none was it so marked as in my own case. Like other doctors, I have had experience of the aspirin-sensitive asthmatic whom aspirin renders violently ill. I have not found it of any value after an asthmatic attack has developed. Though not requiring to do so, I still occasionally take aspirin to prevent the possibility, which may be nothing more than a fear, from the analogy of serum anaphylaxis, of long abstinence causing me to acquire sensitiveness to the drug.

Income Tax

Early Years of New Appointment

H. was appointed as a member of a medical board in 1939. For 1939-40 he received £130 and was assessed on £130; for the two following years the amounts have been respectively: 1940-1, £350 and £350; 1941-2, £200 and £350. Is this correct?

*** 1941-2 is the third year of the appointment, and the basis of assessment is the earnings of the preceding year, but if the earnings fall short of that amount a reduction to the actual basis can be claimed. The assessment of £350 was therefore correctly made, but H. can apply for it to be reduced to the actual figure of £200.

General Expenses of Practice

P. seeks information on the following points:

(1) Professional accommodation. One-half of the total cost of rent, rates, etc., is not now usual. On the other hand, one-quarter hardly seems adequate on the facts stated, especially if the total accommodation includes a garage for a car used professionally. We suggest an offer be made to accept one-third under protest. (2) Cost of maid. When only one maid is in fact kept it may be assumed that she assists in private house-work to some extent, and a claim to deduct her wages is valid only in the proportion her time is spent on the professional side of her total work. That no maid might be kept except for the existence of the professional work is not sufficient to justify a claim to deduct the whole expense; the facts have to be taken as they are, not as they might be. We cannot advise on what weekly sum should be charged for her food; it depends too much on the actual facts of the case. (3) If a medical man does in fact pay his wife reasonable remuneration for her services in assisting in the conduct of the practice (say £1 a week) he can deduct that sum as an expense, and she will not be liable for the tax on it as it is covered by the (£80) allowance for "wife's earned income." But if P. did not do so for 1941, he cannot now claim that he did.

LETTERS, NOTES, ETC.

Hypnosis

Dr. A. OWEN-FLOOD (London, N.8) writes: It is evident in Dr. L. H. Eunson's letter (Sept. 19, p. 353) that he has not made a deep study of hypnotism. I think he emphasizes the evils of the state. May I indicate some of its blessings when applied to cure many minor maladies encountered in general practice. Bed-wetting, nail-biting, and other "habits" soon disappear in a few sittings; care, of course, is taken to deal with any physical causes. Hyperemesis gravidarum, insomnia in the puerperium, and sudden arrest of the lactation can be cured by hypnosis. These conditions, often so trying to the patient, the relatives, and the doctor, are mild anxiety states. Hypnosis is a useful weapon in the armoury of the anaesthetist. The dangerous excitement stage of the induction can be prevented by using hypnosis before the induction, and it is especially easy to apply when the premedication is morphine and scopolamine in the usual doses. Spinal anaesthesia is robbed of all its tendency to produce psychic trauma if a trance state is induced as soon as the tingling and numbness are felt in the legs This seems to render the patient more sensitive to suggestion.

Gastritis in Children and Priority Eggs

Dr. PAUL R. E. KIRBY (Brighton) writes: I am at present attending a child aged 4 who is seriously ill with persistent vomiting and pneumonia. Amongst other forms of treatment albumen water is required. I gave the mother Form EG1/C.1 to take to the local food office, but left the category blank as the condition did not come under A, B, C, or D; I wrote on the back of the form: "Child very seriously ill with vomiting and pneumonia." Eggs were refused for the following reasons: (1) class not filled up; (2) condition did not come under category A, B, C, or D. If this child does not get eggs he may die, and yet an expectant mother in good health and doing a full day's work can get them. It does not make sense. Vomiting in children is one of the commonest conditions encountered in general practice and yet no provision is made for it. May I suggest a fifth category—namely, (E) for children suffering from gastritis and requiring eggs and milk or albumen water.

First-aid Treatment for Fractured Spine

Mr. J. R. M. WHIGHAM (St. Andrew's Hospital, E.3) writes: Lieut.-Col. J. L. Moir's letter (Oct 31, p. 529), in which he suggests a simplified method for the first-aid treatment of fractures of the spine, will be appreciated by all those concerned in this branch of work. Another point on which the guidance of orthopaedic surgeons would be valuable, and one which gives rise to confusion in the minds of students of first aid, is the desirability or otherwise of reducing open (compound) fractures of the limbs before applying splints.

MEDICINE 100 YEARS AGO

The following are answers to correspondents, printed at the end of the *Provincial Medical Journal* for November 12, 1842:

Dr. Hennen's communication, on the Mortality of the Children at the Royal Military Asylum, &c., shall appear in our next number. We have also to acknowledge the receipt of an interesting case of hydatids of the brain, by *Mr. Tanner.*

B.—We are not yet reduced to the necessity of inserting communications from quacks, whether professional or non-professional The gentlemen who inhabit certain "squares" must, therefore, content themselves with the publicity which results from the insertion of their puffs in the "Lancet" and "Medical Gazette." It is really deplorable to see how unwilling men are to practice what they preach.

The requests of *Mr. Walker* and *Philo* have been attended to.

We have received some letters relative to the transmission of the Journal, which have been submitted to the publisher.

Amicus.—We thank *Amicus* for his kindness, and shall be glad to receive the first part for perusal.

A.F.—We refer *A.F.* to our advertising columns. The manual of M. Cazenave is the best *elementary* work that the practitioner can possess. There are more elaborate treatises on diseases of the skin, but the one we allude to is the most practical and convenient one with which we are acquainted.

Z.—Our correspondent's prophecy has been fulfilled; but the poor attempt to revive the *Bat's Club* can at the present day only excite contempt. The time is gone by since a falling journal could be propped up by calumny and impotent sarcasm.

THE TYPHUS GROUP OF FEVERS

CLASSIFICATION, LABORATORY DIAGNOSIS, PROPHYLACTIC INOCULATION, AND SPECIFIC SERUM TREATMENT*

BY

A. FELIX, D.Sc.

(From the Emergency Public Health Laboratory Service)

The "typhus group of fevers," comprising a number of different varieties of the disease, is now firmly established. Typhus researches during the past few years have revealed the occurrence of typhus-like diseases in many parts of the world. Not a few endemic diseases of various tropical and subtropical countries, some of which had long been known under the label "unclassed fevers," have now been recognized as members of the typhus fever group. This recent development is mainly due to the application of serological and immunological methods to the study of these diseases. The so-called Weil-Felix reaction has provided in almost every instance the first evidence of the generic relationship of the unknown disease to classical louse-borne typhus, and thus opened the way for the experimental study which has led to the demonstration of the corresponding rickettsia. Some of the best-known instances of this sequence of events are: the endemic typhus of the United States of America (Maxcy and Havens, 1923); the tropical typhus of the Federated Malay States (Fletcher and Lesslar, 1925); the "fièvre exanthématique" of Marseilles, and "fièvre boutonneuse" of Tunis (Burnet and Olmer, 1927; Felix and Rhodes, 1931; Durand, 1932); São Paulo typhus (Piza *et al.*, 1931; Monteiro, 1931; Felix, 1933a); and the tick-bite fever of South Africa (Pijper and Dau, 1930, 1931, 1932).

The terms "rickettsial infections" and "typhus group of fevers" are not synonymous, the former being much wider than the latter. If the rickettsial infections that occur in certain domestic animals are excluded and only those that affect man are considered, there still remain some rickettsial diseases of man which, according to our present knowledge, seem to be unrelated to the typhus group of fevers. Among these diseases may be mentioned the "Q" fever of Queensland (Derrick, 1937; Burnet and Freeman, 1937) and of certain parts of the U.S.A. (Davis, Cox, Parker, and Deyer, 1938), and the "trench fever" which became known in 1916 as a wartime infection but has not again made its appearance in epidemic form, even during the present war.

Classification

Megaw (1921, 1930) was the first to attempt to classify the typhus-like fevers as members of one group of diseases and suggest a subdivision according to the transmitting insect vector. The suggestion was undoubtedly a step in the right direction, and so long as the group was composed of only a few diseases the differentiation according to vector seemed to fit the known facts. This, however, no longer holds good.

A satisfactory classification of the typhus group can be based solely on the antigenic type of the corresponding rickettsiae, upon which immunity and immunity-reactions depend. The antigenic analysis of the various typhus rickettsiae has, however, not yet passed its infancy. The most widely studied of these organisms is *R. prowazeki*, the causal organism of Old World and New World typhus of type X 19. It is known that *R. prowazeki* possesses a heat-labile and a heat-stable antigen (Castaneda and Zia, 1933), that the latter is common to *R. prowazeki* and *Proteus* OX 19 (Weil and Felix, 1921), and that this O antigenic component is alkali-stable (Bruce White, 1933). The antigenic structure of the rickettsiae of the other varieties of typhus and their relationship to each other have not been studied as yet, owing to the great difficulty in obtaining pure suspensions of rickettsiae in sufficiently large quantities. This difficulty has been overcome only quite recently, thanks to the discovery of two methods of growing rickettsiae—namely, in the yolk sac of the developing chick (Cox, 1938) and in the lungs of infected rats and mice (Castaneda, 1939). There is good reason for believing that as a result of these important advances the gaps in our knowledge will be filled very soon.

So far the serology of the typhus group has been based on the antigenic relationship between the rickettsiae of the different varieties of the disease and corresponding serological varieties of *Proteus* X. This relationship is most strikingly demonstrated by the close correlation between cross-immunity and agglutination reactions with the three types of *Proteus* X

TABLE I—*Provisional Classification of the Typhus Group of Fevers*

Immunological Subgroup }	Type OX 19	Type OX K	Type undetermined
Name of disease .	Classical epidemic typhus Tabardillo (Mexico) Brill's disease (U.S.A.) Endemic typhus of U.S.A and Australia, Greece, Syria, Manchuria, Malay (shop typhus), India, Burma, Philippines, Hawaii, Toulon (fièvre nautique), etc	Tsutsugamushi fever of Japan, Formosa, Malay, and Dutch East Indies Scrub typhus of Malay, Dutch East Indies, India, French Indo-China, Australia	Spotted fever of Rocky Mountains Spotted fever of eastern U.S.A. São Paulo typhus Fièvre boutonneuse (Mediterranean) Fièvre exanthématique of Marseilles Febbre errutiva (Italy) Tick-bite fever of South Africa Epidemic and endemic typhus of South Africa Tick-borne typhus of India, Kenya, etc.
Vector ..	Lice and rat fleas	Mites	Ticks, lice, and rat fleas
Reservoir of virus	Rats Man	Field mice and rats	Rodents. Dogs. ? Ticks. Man
Agglutination ..	OX 19 +++ OX 2 + OX K –	OX 19 – OX 2 – OX K +++	OX 19 + OX 2 + OX K +

---

* A report to the Medical Research Council.

strains, known as OX 19, OX 2, and OX K (Felix, 1933b). The conception of serological varieties of typhus, based on the work of Fletcher and Lesslar (1925) and formulated by Felix and Rhodes (1931), led to the subdivision of the typhus group into three immunological subgroups.

Table I shows that the suggested scheme (Felix, 1935) comprises at present only two well-defined main types—namely, types OX 19 and OX K. The third subgroup, provisionally designated "type undetermined," probably contains several different types. Further subdivision will be made possible by the use of pure cultures of the corresponding rickettsiae, which will disclose the interrelationships of both the heat-stable and the heat-labile rickettsial antigens.

The most important of these diseases is the louse-borne typhus of type OX 19, known as the classical epidemic typhus and caused by *R. prowazeki.* The subsequent sections of this paper deal mainly with this variety of the disease, though some of the conclusions are applicable also to the other typhus-like fevers. A few remarks on nomenclature may not be out of place here. In the past some confusion has arisen from the tendency to use a number of different names to designate the same disease. In recent papers published in this country (Findlay, 1941a, 1941b) this tendency has reappeared, and the louse-borne epidemic typhus has been given a new name—viz., "exanthematic" typhus. It cannot be said that there was need of a new name. The one chosen by Findlay certainly does not offer any advantage over the generally accepted old names. There is nothing distinctive in the name "exanthematic" typhus, since all the varieties of typhus are exanthematous diseases. Louse-borne typhus occurs as an endemic disease in many parts of the world, but gives rise to widespread epidemics only under exceptional conditions, chiefly in the wake of war, famine, or other major disasters that favour louse-infestation. The term "louse-borne typhus," used throughout this paper, applies to both the epidemic and the endemic form of the disease.

Laboratory Diagnosis

The clinical diagnosis of typhus is not altogether easy, so that early guidance is sought from laboratory findings. The following laboratory methods of diagnosing typhus infections have been suggested at one time or another: biopsy of skin lesions, with a view to demonstrating typhus nodules or rickettsiae; inoculation of the patient's blood into guinea-pigs or other laboratory animals; serological tests. The latter alone have proved to be of practical importance. It is, of course, theoretically possible to diagnose a typhus case by isolation of rickettsiae from the patient's blood or from the insect vector, when this has been found on the patient. It is, however, a mistake to recommend these methods for diagnostic purposes (Army Pathology Laboratory Service, Current Notes, 1941). These complicated and rather dangerous procedures would hardly ever enable the pathologist to aid the clinician in diagnosing a case of typhus fever.

Fortunately, the isolation of rickettsiae is not necessary, since the diagnosis of typhus can be confirmed by a relatively simple serological test. The Weil-Felix reaction has been employed for the purpose during the past 25 years. The limited space here available precludes discussion of the technique of the test, its application by the clinician and epidemiologist, its limitations, and the interpretation of results, but it can be stated that practical experience on a very large scale has shown that the *Proteus* OX 19 reaction is the most constant sign of louse-borne typhus; the clinical symptoms, on the other hand, may show very wide variations.

Experiments on agglutination of rickettsial suspensions have been carried out ever since Weigl (1923, 1930) first obtained fairly concentrated suspensions by his method of anal infection of lice, and Zinsser and Castaneda (1932) by intraperitoneal infection of *x*-rayed rats. These experiments, though of outstanding importance in typhus research, have not so far made it possible to adopt agglutination tests with rickettsiae as a routine method of diagnosing typhus cases. The microscopical technique gives unsatisfactory results, while the macroscopic technique requires relatively large quantities of rickettsial suspensions, which can be more usefully employed for the preparation of vaccines. The most recent advances in growing rickettsiae (Cox, 1938; Castaneda, 1939) have not, for the time being at any rate, materially altered the position.

The published data on the agglutination of *R. prowazeki* by the serum of typhus patients and convalescents present a rather confusing picture. Some workers have reported almost complete parallelism between agglutination of *R. prowazeki* and *Proteus* OX 19 (Weigl, 1930; Zinsser and Castaneda, 1932), whereas others obtained quite different results (Liu, Zia, and Wang, 1938; Hudson, 1940). Obviously the confusion is due to the fact that agglutination of rickettsiae can be adequately described only in terms of two separate reactions—namely, those which occur between the heat-labile and the heat-stable antigens and their respective antibodies. According to Castaneda and Zia (1933), living or formolized rickettsiae are not agglutinated by the OX 19 antibody, but become agglutinable after heating at 75° C.; phenol seems to produce a similar effect to heat. Differently prepared rickettsial suspensions, such as have been employed by various workers, do not therefore indicate the same antigen–antibody reaction when tested against typhus sera that contain, or may contain, the two different antibodies.

What has been said about agglutination of rickettsiae applies also to complement-fixation with these organisms (Castaneda, 1936b; Mosing, 1938; Bengtson, 1941; Bengtson and Topping, 1941). Either of the two reactions may be used for the demonstration of the antibody corresponding to the heat-labile rickettsial antigen provided that a technique is devised by means of which the heat-stable O antigen is precluded from taking part in the reaction and thus obscuring the results.

Although the technique of the customary test-tube agglutination with *Proteus* OX 19 is very simple, still simpler procedures have been adopted by workers in the U.S.A. (Welch, 1937) and in Mexico (Castaneda *et al.*, 1940) in the form of slide agglutination tests. German workers even employ a slide test using dried drops of whole blood instead of the separated serum. Extensive surveys are being carried out by this method in endemic areas in occupied Poland, with a view to detecting missed ambulatory patients and cases of so-called inapparent infection. The latter cases are of special epidemiological importance since they do not show any clinical symptoms whatever, but are capable of infecting lice and spreading the disease. The dry-drop blood tests are carried out within a few minutes even under the most primitive conditions, and it is claimed that the results compare favourably with those obtained with test-tube agglutination (Eyer and Grützner, 1939-40; Steuer, 1942).

Immunity to Typhus in Relation to the Known Antigenic Constituents of Rickettsia

Immunity to typhus has been studied in experimental animals for the past 30 years, but is as yet very incompletely understood. The main obstacles to progress have been, and still are, lack of knowledge of the essential antigens of the causal organism and lack of a suitable experimental animal. Most of the work has been done on guinea-pigs and rabbits; more recently rats and mice have come into use. In none of these animals, however, does typhus infection run a course comparable to the disease in man. Only the chimpanzee reacts with symptoms similar to those of a mild case in the adult man. Monkeys of the various lower genera so far tested do not offer any advantage over the guinea-pig as test animal. Quite recently the Eastern cotton rat of the U.S.A. (Snyder and Anderson, 1942) and the common gerbil of South Africa (Gear and Davis, 1942) have been suggested as more susceptible animals, and are now being tried out.

It has been known for a long time that immunity to typhus is complex—that is to say, it is related to more than one antigenic constituent of the causal organism. The O antigen of *Proteus* X 19, which corresponds to the heat-stable antigen of *R. prowazeki,* does not induce immunity to experimental typhus infection, and the corresponding O antibody, though so valuable in diagnosis, does not account for the protective action of convalescent serum from man and animals. A clue to this puzzling problem has been provided by the work of Castaneda (1934, 1935, 1936a, b, c), who showed that *Proteus* OX 19 immune serum reacts with rickettsia only in agglutination, precipitation, and complement fixation, but is inactive in opsonization. It is the antibody to the heat-labile rickettsial antigen that is of outstanding importance in phagocytosis of *R. prowazeki* and in protection against infection with this organism.

It would be wrong, however, to conclude from these experiments that the heat-stable O antigen and its corresponding antibody are not concerned in typhus immunity, because a glance at Table I shows that they are. Cross-immunity between different varieties of typhus rickettsiae is accompanied by identity of the serum reactions to the O antigen of the corresponding *Proteus* X strains, whereas failure to obtain cross-protection coincides with dissimilarity in O agglutination reactions. The results of cross-immunity tests can thus be predicted from the O agglutination tests obtained with various types of *Proteus* X, and have in fact been so predicted (Felix, 1933b). It is also well established that there are two types of the curve of OX 19 agglutinin production in typhus patients, and that these are related to the clinical course of the disease (for references see Felix, 1930).

These facts can be reconciled with Castaneda's findings if it is assumed that the labile antigen of *R. prowazeki* plays a part similar to that of the labile somatic antigen of the typhoid bacillus, known as the Vi antigen. The analogy between the two is indeed very striking, for the typhoid O antigen alone is incapable of inducing in animals effective immunity to infection with virulent Vi + O bacilli, but the Vi antigen is. And, again, typhoid Vi antibody is a powerful opsonizing agent for Vi + O bacilli, but the O antibody is not. *R. prowazeki* and *Bact. typhosum* also show close similarity in the agglutinative properties of their somatic antigens. Living and formolized suspensions of both organisms are not agglutinated by their respective O antibodies but become agglutinable after heating. Breinl (1924) showed that the O antigen of *R. prowazeki* from the louse gut retains its agglutinogenic property after heating at 100° C., as do O antigens generally.

It seems, therefore, quite natural to assume that the O antigen of *R. prowazeki* plays a part similar to that of the O antigen of the typhoid bacillus and other Salmonellas, and of other organisms—namely, that of acting as an endotoxin. The corresponding OX 19 antibody would thus function as an anti-endotoxin (Boivin and Mesrobeanu, 1933; Raistrick and Topley, 1934; Felix and Pitt, 1934). Strong evidence in support of this view is provided by the clear-cut results of intradermal tests with heat-killed suspensions of *Proteus* OX 19 (Friedberger and van der Reis, 1919) or with extracts prepared from *Proteus* OX 19 (Fleck, 1931). In normal persons and non-typhus patients the intradermal injection of OX 19 antigen produces a local inflammatory reaction, reaching its maximum after 24 to 36 hours. Typhus patients react in a similar manner during the first few days of illness, but from the fifth or sixth day onwards the reaction is negative and remains so throughout convalescence and for varying periods, up to several months, after recovery. This period coincides with the presence in the serum of OX 19 agglutinins in significant titre. The toxicity to man of the OX 19 antigen and the specific neutralization of its toxic action as a result of recovery from typhus infection are thus clearly demonstrated.

The latest development in the study of typhus immunity is the demonstration by German workers of a heat-labile rickettsial endotoxin which is lethal to mice and specifically neutralized by convalescent serum from man and animals (Gildemeister and Haagen, 1940; Otto and Bickhardt, 1941). The lability of this toxic substance is much the same as that of the heat-labile rickettsial antigen described by Castaneda, and it seems very likely that the two are identical.

It would appear, therefore, that in two widely separated organisms, such as the typhoid bacillus and the strictly intracellular-virus-like *R. prowazeki*, the mechanisms of infection and immunity are in principle very much alike. In both cases a heat-labile somatic antigen, besides acting as a toxic substance, inhibits the interaction between the O antigen and the O antibody, and thus protects the bacterial, or rickettsial, cell against the opsonizing and bactericidal actions of the natural and immune O antibody. It is not suggested that these are the sole factors associated with immunity to typhus. Antibodies to yet other, still unknown, constituents of the rickettsial cell may also play a part. But it is obvious that the two rickettsial antigens and antibodies that have so far been defined are essential elements in immunity to typhus.

Specific Serum Treatment

Specific serum treatment of typhus fever of recognized value has not yet been evolved, and attempts at chemotherapy so far have also been unsuccessful. One of the German typhus experts working in Warsaw since 1940 recently reported that trials with nearly 100 different drugs, including 24 sulphonamide compounds, gave only negative results (Wohlrab, 1942). French workers who have had many years' experience of louse-borne typhus in Tunis consider treatment with sulphapyridine not only useless but even harmful (Durand and Balozet, 1941).

Convincing therapeutic effects have not been observed with convalescent serum, although such sera usually exert a definite prophylactic action when tested on the guinea-pig. Wohlrab (1942) found pooled convalescent serum ineffective not only in the treatment of typhus cases but even as a prophylactic when employed during a prison epidemic in Poland.

Durand and Balozet (1941) treated a series of 120 cases of louse-borne typhus in Tunis with serum from horses immunized with living rickettsiae from infected mouse lung and believed that they obtained evidence of its beneficial effects. It is, however, rather disappointing to note from their paper that only the indigenous patients seemed to respond to the treatment, while the European patients did not. Wyckoff and Bohnel (1942), using a strongly concentrated serum from immunized rabbits, described therapeutic effects in guinea-pigs infected with louse-borne typhus. The data published by these workers do not, however, warrant their conclusion, since the serum was in each instance administered before the onset of fever. The present position, therefore, is that there is no convincing evidence of the curative action of the so-called therapeutic sera, although their prophylactic value in animal experiments has been established beyond doubt.

In the light of the facts discussed in the preceding section it would appear that the efficacy of a therapeutic anti-typhus serum depends upon the presence in it of effective amounts of the two different antibodies corresponding to the heat-labile and heat-stable rickettsial antigens. It is, however, quite clear that sera of this kind have not yet been employed in the treatment of typhus patients. Convalescent sera cannot be obtained sooner than two or three weeks after defervescence, by which time the OX 19 titre has fallen to a mere fraction of its maximum value. In louse-borne typhus this maximum is usually reached a day or two before or after the first day of defervescence. There can be little doubt also as to the deficiency in O antibody content of the therapeutic immune sera so far prepared. Durand and Balozet (1940) showed that prolonged hyperimmunization of horses and donkeys in no instance resulted in an increase in the low-titre OX 19 antibody which each of the animals had developed at the very beginning of the immunization. While the titre of the neutralizing antibody rose that of the OX 19 antibody fell, although the doses injected contained enormous numbers of rickettsiae.

TABLE II.—*Showing OX 19 Agglutinin Titres of Therapeutic Anti-typhus Sera and Sera from Horses Immunized with Proteus OX 19 Antigen*

Serum	Antigen used for Immunization	OX 19 Agglutinin Titre
Anti-typhus serum (horse) (Durand and Balozet, 1940)	*R. prowazeki* from mouse lung. Tunisian louse-borne strain	1:100
Anti-typhus serum (rabbit, concentrate) (Wyckoff and Bohnel, 1942)	*R. prowazeki* from egg-yolk sac. European louse-borne strain	1:30
Horse 1	*Proteus* OX 19 alkali-treated	1:60,000
" 2	"	1:40,000
" 3	"	1:20,000
" 4	"	1:5,000

This difficulty may possibly be overcome by producing the O antibody by immunization with the O antigen of *Proteus* X 19. Horses are now being immunized at the serum department of the Lister Institute at Elstree in collaboration with Dr. G. F. Petrie. The immunizing material was designed to contain in concentrated form the alkali-stable O antigen of *Proteus* X 19, which, according to Bruce White (1933), is common to both *R. prowazeki* and *Proteus* X 19. Table II shows the OX 19 titres of the serum from horses immunized in this way. For comparison the OX 19 titres of the therapeutic sera prepared by Durand and Balozet (1940) and by Wyckoff and Bohnel (1942) have also been included in the table.

Three of the four horses immunized with OX 19 antigen developed titres higher than those usually met with in recovered typhus patients. The titres also compare favourably with the titre of the typhoid O antibody in therapeutic anti-typhoid serum (Felix and Petrie, 1938). It is known that the strong antitoxic activity of anti-typhoid Vi + O serum is mainly due to its anti-O component, and it seems worth while trying whether a potent OX 19 immune serum will exert a similar effect in cases of typhus fever.

It is hoped that a supply of this serum will shortly be available for clinical trial along with anti-rickettsia serum. Evidence of the efficacy of such treatment cannot be obtained from animal tests, since none of the experimental animals develops toxic symptoms comparable to those of louse-borne typhus in man. Anti-OX 19 serum should, of course, be tried in combination with anti-rickettsia serum containing neutralizing antibody in high titre. The relative importance of the effects of each of the two antibodies on the course of the disease can be assessed only by clinical trials on typhus patients.

Prophylactic Immunization

Immunization against louse-borne typhus is still in the experimental stage. It is only two or three years since methods of growing rickettsiae in large quantities have been developed. Vaccine made from the gut of infected lice (Weigl, 1930) is the only type of killed typhus vaccine that has, so far, passed its test for efficacy in the field. Unfortunately this vaccine is too difficult to make on a large scale. Most of the workers in America favour the use of rickettsiae grown in the yolk sac of developing chick embryos (Cox, 1938); French workers follow the method of Castaneda (1939) and grow the rickettsiae in the lung of infected mice or rabbits (Durand and Giroud, 1940). In Germany all three techniques are apparently employed.

A number of other problems of importance still remain to be solved before typhus vaccines of maximum prophylactic value can be obtained. One of these is the question how the labile rickettsial antigen can best be maintained in the cultures. The best methods of killing and preserving the vaccines have also yet to be found. At present phenol and formalin are employed. It is known that typhoid vaccines prepared in this way do not contain the labile Vi antigen in its most efficient form (Felix, Rainsford, and Stokes, 1941), and it is quite probable that the labile rickettsial antigen also is damaged by phenol and formalin.

The customary methods of testing the efficacy of typhus vaccines are active immunization of guinea-pigs and tests for OX 19 and neutralizing antibodies in the serum of inoculated subjects. It is not advisable to rely on any one of these tests as the sole method of assay. All three types of test should be employed when differently prepared vaccines are compared.

Tests of OX 19 agglutinin response were recently carried out on a number of volunteers in this country. The subjects were members of selected hospital staffs and sanitary personnel who were being inoculated under a scheme organized by the Ministry of Health in consultation with the Medical Research Council.* The immunizing course consisted in each instance of three doses of the size recommended by the various laboratories issuing the vaccines. Each volunteer had a sample of blood withdrawn before receiving the first dose of vaccine; a second sample was taken a fortnight after the third dose. Any rise in OX 19 agglutinin titre of 100% or more was taken to be a "significant" increase in antibody content. The results are summarized in Table III.

The table shows that the antigenic value of the various vaccines, as judged by the O antibody response, differed very much. Rabbits injected intravenously with the same vaccines failed to disclose any significant difference; all responded with OX 19 antibody formation.

TABLE III.—*Showing the OX 19 Agglutinin Response in Volunteers Inoculated with Various Typhus Vaccines. (Nov., 1941, to March, 1942)*

Vaccines			Number Inoculated	Number and Percentage showing Significant Rise in OX 19 Agglutinin Titre	
Batch	Prepared from Rickettsiae grown in	Prepared or Issued		No.	%
A	Yolk sac. European louse-borne strain	Oct., 1940	68	3	4.4
B	" "	10/5/41	144	25	17·3
C	" "	4/11/41	125	62	49 6
D	Mouse lung. Tunisian louse-borne strain. (Dr. G. M. Findlay)	1/11/41	16	3	18·7
E	Rat lung. American murine strain	Date of expiry, April, 1943	12	0	0

Neutralization tests of the sera from the various vaccine groups have not yet been carried out, but it is hoped the results will be available for publication at a later date. It is possible that phagocytosis tests may eventually be employed for the quantitative estimation of the antibody to the labile rickettsial antigen, since the O antibody, according to Castaneda (1936a), does not take part in the opsonization of *R. prowazeki*.

Recent reports from Germany emphasize the fact that a death from louse-borne typhus has not yet been recorded in a patient who had been fully immunized with Weigl's vaccine. Very encouraging results also have been obtained in Rocky Mountain spotted fever, the most malignant variety of typhus, by the use of a similar vaccine prepared from infected ticks. Parker (1941), summarizing the results of 15 years' experience of his tick vaccine, showed that the case-fatality rate was 82.3% in non-vaccinated cases in adults but only 8.1% in fully vaccinated cases. Unsuccessful vaccination experiments of earlier workers seemed to suggest that the rickettsiae in the arthropod vector may have some peculiar properties which rickettsiae in the tissues of man and mammals do not possess. It now appears to be likely that the differences are quantitative rather than qualitative: If this is so, one is justified in expecting *R. prowazeki* from animal tissue to yield vaccines of an efficacy equal to that of Weigl's louse vaccine.

Summary

The serological diagnosis and the classification of the fevers of the typhus group are based, so far, on the heat-stable O antigen which is common to the various types of *Rickettsia* and the corresponding types of *Proteus* X. Further subdivision will be made possible by the study of the heat-labile rickettsial antigen.

The roles of the two rickettsial antigens in typhus immunity are very similar to those played by the Vi and O antigens in immunity to typhoid fever.

Therapeutic anti-typhus sera, as at present prepared, contain only negligible amounts of the O antibody. The use of *Proteus* OX 19 immune serum, in combination with anti-*R. prowazeki* serum, is suggested for the treatment of cases of louse-borne typhus.

The methods of preparing and testing typhus vaccines are discussed.

CIRCUMCORNEAL INJECTION AS A SIGN OF RIBOFLAVIN DEFICIENCY IN MAN

WITH AN ACCOUNT OF THREE CASES OF ARIBOFLAVINOSIS

BY

HAROLD SCARBOROUGH, M.B., Ph.D.

(*From the Clinical Laboratories and Medical Out-patient Department of the Edinburgh Royal Infirmary*)

From the heterogeneous collection of signs and symptoms called pellagra a number of specific syndromes are gradually becoming distinct. In 1938-9 Sebrell and Butler first described the specific syndrome of riboflavin deficiency in man, characterized by undue redness of the buccal mucous membrane at the angles of the mouth, by softening of the skin and subsequent fissuring at those angles, and by reddening, fissuring, and desquamation of the vermilion areas of the lips. Similar lesions were observed in the vestibule of the nose and involving the alae nasi and naso-labial folds; and seborrhoeic lesions of the nose, eyelids, and ears were frequent. These findings were confirmed by, among others, Sydenstricker, Geeslin, Templeton, and Weaver (1939), who drew attention to an associated dermatosis which was seen in 2 cases out of 6. A skin lesion, apparently similar, has since been noted by Duckworth (1942). In 1940 Kruse, Sydenstricker, Sebrell, and Cleckley added a further sign—viz., a specific glossitis, different from the red atrophic tongue of the pellagrin in that the organ is purple or magenta in colour, clean, with "flattened or mushroom-shaped" papillae and frequently fissured. They described for the first time ocular lesions characterized by circumcorneal injection, conjunctival congestion, and keratitis. Vascularization of the cornea followed by infiltrations and opacities had previously been described in ariboflavinosis in rats by Bessey and Wolbach (1939). All the above stigmata have been repeatedly resolved by riboflavin but not by any other vitamin, and all except the dermatoses have been produced as the result of experimental feeding.

The ocular manifestations of ariboflavinosis were more fully described by Sydenstricker, Sebrell, Cleckley, and Kruse (1940), who found by means of slit-lamp examination of the cornea that a superficial vascularizing keratitis was the principal ocular manifestation of ariboflavinosis in man. Definite ocular changes could be observed in subjects presenting no evidence of cheilosis or glossitis. Photophobia, blepharospasm, dimness of vision, burning sensations in the eyeballs, "roughness" of the eyelids, and extreme visual fatigue were frequent symptoms, and impairment of visual acuity in the absence of any refractive error or opacity was also described. The earliest and most common ocular sign was found to be circumcorneal injection, which, though "often grossly visible," could always be discerned with the slit-lamp microscope, which revealed actual invasion of the cornea by capillaries in 37 out of 47 cases. Gross injection of the vessels of the fornix and sclera without evidence of infection was also common (43 out of 47 cases). Certain changes in the iris (frank iritis, congestion and pigmentation of the iris) were observed, but much less frequently. Many of these lesions resemble, but are actually distinct from, the ocular manifestations of avitaminosis-A.

Among the series of 47 cases described by Sydenstricker *et al.* (1940) was a group of 18 apparently well-nourished institutional employees, 14 of whom were between the ages of 20 and 35. Only 3 of them were taking "restricted" diets on account of intercurrent disease. All these subjects were considered to have circumcorneal injection, and in addition 13 showed evidence of corneal vascularization when examined with the slit-lamp. On account of this striking finding, but also because of the relative ease with which circumcorneal injection may be detected, it was thought worth while to determine the incidence of this sign in a series of individuals of the hospital class. The results of such an investigation are now presented because of their striking nature, because we believe that the experience of other workers will have been similar, and in order to draw attention to the care which is necessary before circumcorneal injection can be ascribed to ariboflavinosis.

Material and Methods

The investigation was undertaken on a series of 204 cases seen during the routine work of the medical out-patient department of the Edinburgh Royal Infirmary between Oct., 1941, and March, 1942—i.e., during the season when the highest incidence of deficiency disease might be expected to occur. The ages of the patients, none of whom suffered from any ophthalmic infection, varied from 12 to 69. Each subject was examined for circumcorneal injection according to the description given by Sydenstricker and his colleagues, but in no case was the slit-lamp used, and no detailed examination for other stigmata of vitamin deficiency disease was made except in 8 selected cases referred to later. The great majority of the patients suffered from chronic organic disease, but, so far as is

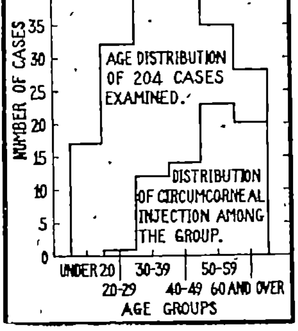

Chart showing incidence of circumcorneal injection, in reference to age, among 204 cases.

known, none was febrile when examined. Cases of frank vitamin deficiency disorder (2 cases of scurvy, 1 of frank ariboflavinosis, and 1 of pellagra with hypochromic anaemia) are not included in the analysis, but are referred to specifically below.

The riboflavin used in this investigation was "lactoflavin" Roche, supplies of which were made available by Roche Products Ltd. Particular care was taken to ensure that the material was protected from the light, strict instructions on this point being given to all patients.

Results

Out of 204 cases examined, 70 (34.3%) presented evidence of circumcorneal injection. On further analysis the physical sign was seen to be unevenly distributed through the series, occurring with relatively greater frequency in the older patients (see Chart). Among subjects aged 50 or over (63 cases) circumcorneal injection was found in 43 (68%). These striking findings might at first be taken to indicate that one-third of all the patients, and two-thirds of the patients over 50, manifested evidence of ariboflavinosis. This interpretation, even taking into account that the investigation was made during the winter and early spring of the third year of war, seemed to us untenable and to require further consideration of the possibilities involved. Essentially these seem to be (*a*) that we have not interpreted the description of Sydenstricker and his co-workers correctly, or (*b*) that circumcorneal injection cannot always be taken as evidence of ariboflavinosis. It is possible also that we may have erred on both counts. It was accordingly felt that a more detailed examination of a small number of cases would be of value. This was undertaken from two points of view, as follows:

1. On the basis of their willingness to co-operate, 8 subjects were chosen from the above series for more complete investigation, the results of which are briefly set forth in Table I. None of these patients suffered from obvious disease of the alimentary tract, and all were taking a usual diet, apparently adequate for their caloric, protein, vitamin, and iron requirements. They were instructed to make no alterations in their way of living during the period of investigation. With the possible exception of Case 1, there was no obvious difference in the degree of circumcorneal injection during or after oral or parenteral riboflavin therapy. Two cases given brewer's yeast after treatment with riboflavin also failed to improve.

TABLE I.—*Showing Results of Riboflavin Treatment of 8 Subjects with Bilateral Circumcorneal Injection*

Case	Sex and Age	Diagnosis	Other Ocular Symptoms and Signs	Other Stigmata of Possible Deficiency Disease	Riboflavin Therapy	Dosage (mg.)	Result
1	M 53	Chr. bronchitis. Emphysema	"Itchy" eyes	Dry, atrophic, pigmented skin	Oral 6 mg p.d. for 20 days	120	? Nil. "Eyes feel a little clearer"
2*	F 69	None made	Unequal and irregular pupils. Previous history of iritis	Bruises easily. Undue fatigue	Oral 12 mg. p.d. for 7 days, then I.M. 10 mg. p.d. for 6 days	144	Nil
3	M 48	Lumbar fibrositis	Nil	Nil	I.M. 2 × 10 mg. on first day, then oral 6 mg. p.d. for 14 days	104	Nil
4†	F 54	Colloid goitre. Auricular fibrillation	Eyes easily fatigued	Nil	Oral 6 mg. p.d. for 27 days	162	Nil
5	F 46	Obesity and glycosuria	? Allergic conjunctivitis in spring	Nil	Oral 3 mg. p.d. for 10 days, then 6 mg. p.d. for 10 days, then 12 mg. p.d. for 6 days	162	Nil
6	M 40	Chr. (left) pyelonephritis. Under urological investi ation	Nil	Nil	Oral 6 mg. p.d. for 14 days; 4 I.M. injections 10 mg.	124	Nil
7	M 42	Pleurisy. Unresolved pneumonia	Nil	General debility	Oral 6 mg. p.d. for 14 days, then brewer's yeast 2 oz. p.d. for 14 days	84+	Nil
8	M 50	Chr. bronchitis. Emphysema	Rapidly progressive presbyopia. Marked arcus senilis	Nil	Oral 6 mg. p.d. for 14 days, then brewer's yeast 2 oz. p.d. for 10 days	84+	Nil

* Gave a previous history of aphthous stomatitis four years ago.
† This patient was taking digitalis during the latter part of the investigation.
The riboflavin content of brewer's yeast is given by Fixsen and Roscoe as 1·5 mg. per 100 g.

TABLE II.—*Effect of Riboflavin Therapy in 8 Cases of Frank Vitamin Deficiency with Circumcorneal Injection*

Case	Sex and Age	Diagnosis	Other Signs and Symptoms of B-complex Deficiency	Riboflavin Therapy	When Given	Dosage (mg.)	Result
9	M 71	Scurvy	Peripheral neuritis. Sore tongue. Dry scaly skin*	Oral 6 mg. p.d. for 22 days + 2 I.M. injections of 10 mg. each	After ascorbic acid 5 9 g. and thiamin 0 35 g.	150+	? Nil
10	M 61	Scurvy	Nil	Oral 6 mg. p.d. for 28 days, with brewer's yeast 20 g. p.d. for 14 days	With ascorbic acid 500 mg. p.d. for 7 days	162+	Nil
11	M 58	Scurvy	Peripheral neuritis. Aphthous stomatitis. Dry scaly skin. Cured by brewer's yeast	Oral 6 mg. p.d. for 14 days	After ascorbic acid 3·5 g. and hesperidin 9 6 g.	84	Improved
12	M 60	Scurvy	Paraesthesiae; numbness in both feet later ? cured by thiamin	Oral 6 mg. p.d. for 14 days + I.M. injection of 10 mg.	After ascorbic acid 3·6 g. hesperidin 48 g.	94	Improved
13	F 48	Hypochromic microcytic anaemia	Bright-red painful tongue. Buccal ulceration. Rough pigmented skin elbows and wrists†	I.M. 5 mg. p.d. for 10 days	With $FeSO_4$ 9 g. p.d. and ascorbic acid 200 mg. p.d.	50	Cured
14	M 40	Scurvy	Marked peripheral neuritis and oedema responding to thiamin. Stomatitis. Sore tongue	I.M. 5 mg. and 10 mg. on alternate days	After ascorbic acid 5·5 g. and thiamin 0·35 g.	50	Cured
15	M 60	Scurvy	Nil	I.M. 5 mg. p.d. for 7 days, then brewer's yeast 2 oz. p.d. for 26 days	After ascorbic acid 6 g.	35+	Nil
16	M 40	Pellagra	Diarrhoea. Stomatitis. Red, raw, atrophic tongue. Thick dry pigmented skin †	I.M. 10 mg. p.d. for 5 days, then 12 mg. p.d. orally for 14 days	After ascorbic acid 5 g. and nicotinic acid 4·2 g.	218	Cured

* Circumcorneal injection very marked. No evidence of infection. Photophobia and blepharospasm, "roughness" of the eyes and undue visual fatigue all improved by riboflavin. Other signs and symptoms resolved by brewer's yeast or nicotinic acid.
† All cured by nicotinic acid.

It is clear, therefore, that a form of circumcorneal injection exists which is not cured by riboflavin even in large doses. In 8 cases this was not found to be associated with other evidence of riboflavin deficiency or with other stigmata of deficiency disease. It cannot, therefore, be ascribed to ariboflavinosis. It may be observed in this connexion that Youmans (1941) has evidently observed a number of cases of angular stomatitis (cheilosis), indistinguishable from those due to riboflavin deficiency, which failed to respond to oral or parenteral riboflavin therapy. He considered that these cases were unlikely to be due to riboflavin deficiency.

2. A second group of 8 subjects, all of whom presented evidence of frank vitamin deficiency disease, were studied in order to determine (*a*) whether circumcorneal injection similar in appearance to that already noted could be detected, and (*b*) whether riboflavin could resolve the abnormality. Table II summarizes the results of this investigation. Circumcorneal injection could be detected in all these cases; we have, however, records of subjects suffering from frank vitamin deficiency disease, especially scurvy, who do not show this clinical sign. Six of the 8 cases presented in addition other evidence of deficiency of the B-complex vitamins: of these, 3 were cured and 2 definitely improved in respect of circumcorneal injection by riboflavin therapy, the other manifestations of B-complex deficiency afterwards yielding to thiamin, nicotinic acid, or brewer's yeast. One case with marked circumcorneal injection showed no improvement from riboflavin or brewer's yeast, although other stigmata of B-complex deficiency were resolved and there was considerable, and almost certainly genuine, symptomatic relief (see footnote to Table II). Two cases of scurvy without evidence of B-complex deficiency had circumcorneal injection but did not respond to riboflavin therapy or to brewer's yeast.

It is clear, from the study of these cases, (*a*) that circumcorneal injection, even when associated with frank vitamin deficiency disease, cannot always be resolved by riboflavin, and is therefore not necessarily a stigma of ariboflavinosis; and (*b*) that a form of circumcorneal injection exists which is resolved by riboflavin but which has been, in our experience, invariably associated with other stigmata of B-complex deficiency. This latter finding confirms in part the observations of Sydenstricker and his colleagues, but seems to point to the fact that circumcorneal injection (as interpreted by us) is not in itself evidence of ariboflavinosis. The physical sign requires to be supported by other evidence of deficiency of the B-complex vitamins, or possibly by examination of the cornea by slit-lamp microscopy—a procedure of which we have no experience.

Further confirmation of these findings and of the classical description of clinical ariboflavinosis by Sydenstricker *et al.* is provided by the following 3 cases of the fully developed deficiency syndrome.

Illustrative Cases

Case 17.—This patient, a woman aged 53, had complained of the symptoms of flatulent hyperchlorhydric dyspepsia with considerable epigastric pain for some three months, together with recent loss of weight and constipation. On investigation she was found to have a small, probably benign, ulcer on the lesser curvature of the stomach. She had been dieting herself for many years. When examined she had photophobia, "roughness" of the eyes, "itchiness" of the lids, and undue visual fatigue for which she had recently been bathing her eyes each evening. Mild blepharospasm, marked reddening of the ciliary margin, and circumcorneal injection were also present. She had aphthous stomatitis and a painful fissure at the right-hand angle of the lips. Her tongue, which was often sore, was pale, smooth, and atrophic. She had recently become a little breathless on exertion, and had a resting pulse rate of 100 a minute and a blood pressure of 110/68 with no evidence of cardiovascular disease. Recently lassitude, depression, and undue fatigue, with pains across the shoulders and down the right arm, had been additional features of the case. This patient's ocular signs and symptoms were rapidly resolved by riboflavin in doses of 12 mg. daily by mouth. Thereafter, regulation of the diet, with the administration of brewer's yeast in doses of 1/2 oz. four times a day, produced remarkable clinical improvement. Pain disappeared within 2 to 3 weeks. She had much more energy and was able to climb stairs without dyspnoea. The resting pulse rate fell to 70–80, and the blood pressure increased to 128/80. The aphthous stomatitis was much improved but not cured. Four weeks after stopping brewer's yeast, and while she was still taking what appeared by normal standards to be an adequate diet, she developed circumcorneal injection, "roughness" of the eyes, and mild photophobia. These again responded to riboflavin treatment.

Case 18.—A woman aged 56, with steatorrhoea following multiple abdominal operations. She had had cheilosis intermittently for two years. On examination there was marked and multiple fissuring at both angles of the mouth, in the naso-labial folds, and at the lateral canthus of both eyes. She had a very painful aphthous stomatitis with dysphagia, and a smooth, pale, tender tongue. Circumcorneal injection was present together with "roughness" of the eyes and impaired visual acuity. Oral administration of riboflavin, 6 mg. daily for 6 days, produced considerable improvement, and daily intramuscular injection of 5 mg. for 10 days completely cured the cheilosis, circumcorneal injection, and ocular symptoms. The aphthous stomatitis, and especially the sore tongue, were not resolved by riboflavin, but responded to nicotinic acid in daily doses of 200 mg. by mouth. All the symptoms returned within 14 days after discontinuing the therapy, even although the diet, by normal standards, was more than adequate in respect of vitamins of the B complex.

Case 19.—This patient, a man aged 69, had been treated intermittently for "pernicious anaemia" since 1916, and for the last 10 weeks had been having injections of liver extract (pernaemon) every 14 days. At the beginning of the present investigation the Hb was 12.2 g. per 100 c.cm. (88% Haldane), with R.B.C. 4,000,000 and C.I. 1.10. He had been complaining for some six months of debility, lassitude, undue fatigue, and vague pains across the shoulders, down the arms, and in the back of the neck. For several years, especially in the winter and early spring, he had had a scaly non-erythematous skin lesion on the calves of the legs, forearms, and back of the hands that was always intensely itchy. On examination a dry "branny" skin was found, with perifollicular keratitis in both upper arms, patchy pigmentation on the back of both hands, forehead, and face, and deformed, ribbed, and very brittle finger-nails. Circumcorneal injection was present, associated with "roughness" of the eyes, some photophobia, and a previous history of iritis, of which residual evidence remained. There was marked cheilosis at the angles of the mouth but none elsewhere. The appearance of the tongue was very striking, the organ being large, somewhat painful and tender, irregularly fissured with large flattened papillae, and magenta in colour. The characteristic purple hue of the tongue in ariboflavinosis can be appreciated best if the organ is inspected within the mouth, where its colour can be viewed against the background of the palate. The tongue of the typical pellagrin appears relatively small and rough, and is redder than the palatal mucous membrane. The tongue in ariboflavinosis appears relatively large and smooth. It is, however, deeply fissured and strikingly more purple than the mucous membrane of the palate and cheek.

After several examinations at weekly intervals, during which no significant alteration in the clinical picture occurred, riboflavin 6 mg daily by mouth was given. After 30 mg. considerable clinical improvement was noted in respect of the ocular changes, cheilosis, glossitis, and dermatosis. In particular, circumcorneal injection was completely resolved. This improvement occurred in spite of the fact that the patient had been receiving every 14 days an injection of liver extract which probably contains some riboflavin. Further treatment by 2 oz. of brewer's yeast daily maintained the clinical improvement, and appeared, after two weeks' administration, to have had a favourable effect on the dermatosis. The perifollicular keratitis was not, however, improved. The patient was seen again 26 days after all therapy had been discontinued. His general health had improved considerably, but cheilosis, glossitis, and circumcorneal injection were again present.

Discussion

A striking feature of the clinical course of the above three cases has been the relatively rapid return, within 2 to 4 weeks after treatment had been stopped, of symptoms and signs (viz., cheilosis, glossitis, circumcorneal injection, and ocular symptoms) which are evidently to be ascribed to riboflavin deficiency, since they are identical with those described by Sebrell and Butler, and by Sydenstricker and his colleagues, and which, furthermore, have responded (in one case on two occasions) to treatment with riboflavin. In 18 out of the 47 cases referred to by Sydenstricker *et al.* (1940) relapse occurred shortly after riboflavin therapy had been discontinued. Apart from 15 apparently healthy individuals whose diets could not be regarded as deficient or unusual, the majority of their cases were taking a frankly deficient diet. Analysis of the diets taken by Cases 17, 18, and 19 of the present series reveals that Cases 17 and 18 were certainly receiving between 2 and 4 mg. of riboflavin a day—on at least 3 days a week in Case 17 and daily in Case 18. Case 19 took a diet which could not be criticized on any ground, and in addition received 2 c.cm. of liver extract every other week.

A possible interpretation of these findings is that the riboflavin requirements of certain individuals are unusually great, as the result either of abnormal utilization or of defective absorption, or both. The idea that synergistic reactions in respect of other vitamins condition the absorption and utilization of riboflavin must be taken into account in evaluating this possibility. Although the results of the present investigation may be taken to indicate the existence of at least two types of circumcorneal injection, only one of which is resolved by riboflavin therapy, an alternative interpretation would appear to be that the development of circumcorneal injection is conditioned by a number of limiting factors, only one of which is a relative deficiency of riboflavin in the diet. In the latter connexion it is of interest to recall the findings of Albanese and Buschke (1942), who observed the clinical manifestations of ariboflavinosis in rats occurring as the result of a lack of tryptophane in their diet. A relationship between the metabolism of protein and another vitamin of the B complex is indicated by the work of Banerji (1941), who found that the presence of a large amount of protein in the diet of rats prevented the bradycardia and loss of weight usually associated with thiamin deficiency, and also that the growth rates of rats on various graded levels of vitamin B_1 were better in each case with excess of protein than without it.

Summary and Conclusions

In a series of 204 unselected out-patients between the ages of 12 and 69 circumcorneal injection was observed in 70 cases (34.3%). In 63 of those aged 50 or over circumcorneal injection was found in 43 (68%).

The observations of Sydenstricker *et al.* on the occurrence of circumcorneal injection in ariboflavinosis have been confirmed, but a form of the condition exists even in subjects presenting evidence of frank vitamin deficiency disease which cannot be attributed to a deficiency of riboflavin, as it is not resolved by administration of the vitamin. The latter finding no doubt accounts for the relatively high incidence of circumcorneal injection observed.

Although circumcorneal injection may be an early stigma of ariboflavinosis it cannot be considered such unless supported by other clinical findings—cheilosis, glossitis, dermatosis, and ocular symptoms—or by slit-lamp examination of the cornea (Sydenstricker *et al.*). The result of a therapeutic test, however, probably still remains the best criterion.

Three cases of ariboflavinosis are described, and it is suggested that certain subjects manifest a requirement for riboflavin which, for reasons unknown, is unusually large.

ADDENDUM.—Since completing this paper we have had the opportunity of discussing the matter with Dr. Sydenstricker, who has seen with us several cases of ariboflavinosis confirmed by slit-lamp microscopy. It is evident that the circumcorneal injection which forms the basis of this communication differs in no material way, on purely clinical examination, from that described by Sydenstricker in frank ariboflavinosis.

DOCTORS FROM OVER-SEAS: HOSPITALITY AT L.C.C. HOSPITALS

The London County Council is offering hospitality at its hospitals to Service doctors and nurses from the U.S.A., Canada, Australia, New Zealand, South Africa, etc. Details of the arrangements have been sent to the various authorities concerned. There may be, however, doctors and nurses who will not hear about it through official channels, and also there may be some from the countries mentioned who are serving with the British Forces. Any such who would like to visit L.C.C. hospitals or stay there during short leave should get into touch with the Medical Officer of Health, London County Council, County Hall, S.E.1 (telephone WATerloo 5000, extension 6425).

SULPHONAMIDES USED LOCALLY

THEIR ABSORPTION FROM SEROUS CAVITIES AND WOUNDS IN MAN

BY

FRANK HAWKING, D.M.
Of the National Institute for Medical Research

AND

ALAN H. HUNT, D.M., M.Ch., F.R.C.S.
Recently Temporary Assistant Surgeon at St. Bartholomew's Hospital

The sulphonamides are the most satisfactory of the drugs at present available for use in preventing the development of infection in contaminated wounds. There is evidence to show that they are more effective when used locally in the wound than when they are given by mouth or parenterally, owing to the greater concentration at the site of potential infection. The local effects of these compounds depend on their individual bacteriostatic powers, and their physical properties. To be of benefit the selected drug or mixture of drugs should be present in the wound fluids in sufficient concentration and for long enough for the infection to be wiped out or for the normal tissue reactions to obtain control of the situation. The rate of absorption of sulphonamides from wounds is therefore of importance, and the present study was undertaken to investigate this problem. As the work was interrupted by the change of appointment of one of the authors the results presented are unfortunately incomplete.

Methods.—Observations were made on patients undergoing operations, many of which were abdominal. Before the peritoneum was closed the sulphonamide was introduced in measured quantities. Powders were sprinkled or dumped into the cavity out of a small container and spread with the finger. Solutions and suspensions were inserted through a catheter, around which the peritoneum had been almost closed; in this way little or none of the drug was lost. The subsequent absorption was followed by taking blood samples at 6, 24, and 48 hours and by measuring the excretion in the urine.

Results

The results in 25 cases are shown in the accompanying table. These include 8 cases observed by Prof. R. S. Pilcher. Nearly 60 other cases were observed clinically, but they have been omitted from this table as the records are incomplete in some particular or other. The first group consists of 11 patients who received 5 g. of sulphanilamide powder. This group comprised 6 abdominal operations, 3 thoracoplasties (2 on children), 1 nephrectomy, and 1 wound of the forearm. The blood and urine figures varied somewhat irregularly, without particular reference to the nature of the operation; for conciseness they are given as an average. Three other cases received 7.5 to 10 g. and a fourth case 15 g., and the concentrations in the blood and urine were somewhat higher. It is seen that when 5 to 10 g. of sulphanilamide is placed in the peritoneal cavity most of the urinary excretion occurs during the first two days. An effective blood concentration was maintained for 24 hours, the maximum reading (at 6 hours) corresponding in this series to about 0.5 to 1 mg. per 100 c.cm. for each gramme of sulphanilamide inserted.

Three patients received 5 to 7.5 g. of "hypoloid sulphanilamide L.S.F." intraperitoneally. This is a Burroughs Wellcome preparation consisting of 15% sulphanilamide in solution as sulphanilamide lactoside sodium formaldehyde sulphoxylate, and it is intended for intramuscular injection. As seen from the table, most of the urinary excretion occurs during the first twelve hours, and probably bacteriostatic activity in the peritoneum is too brief for the optimum results to be obtained.

In 2 cases a wound was packed with gauze and an oil-in-water emulsion, Preparation C, made by the British Drug Houses Ltd. (sulphanilamide 30, beeswax 0.7, cod-liver oil 49, oleic acid 3.6, sodium hydroxide 0.5, water to 100 parts—Fuller, Hawking, and Partridge, 1942). In animals it has been found that the presence of the oil delays absorption, provided that the surface is small compared with the volume, as in the present instance. In these two cases the results are rather irregular, but after 5 to 6 days the dressing still contained considerable quantities of sulphanilamide. In a third case a small deep wound was packed with gauze plus a preparation consisting of sulphanilamide 30%, cod-liver oil 60%, and beeswax 10%, about 4 g. of sulphanilamide being inserted; the blood concentration at 24 hours was free 1.1, total 1.7 mg. per 100 c.cm., and during the next 5 days the daily excretion of sulphanilamide in the urine was about 0.2 to 0.4 g.; when the dressing was removed on the fifth day it contained about 0.2 g. of the compound. It should be noted that further histological study of experimental wounds has led us to the conclusion that all types of oil which may become embedded in a wound lead to undesirable tissue reactions and that cod-liver oil is particularly deleterious in this respect (Hawking, 1942).

Six patients received sulphadiazine inserted as a microcrystalline suspension (Chambers *et al.*, 1942), and the results with 4 of them are shown in the table. The blood concentrations in these cases were high, but the urinary excretion was less prolonged than animal experiments had led us to expect. The effect of this treatment on the clinical condition seemed to be good, allowing for the grave nature of these cases. Two of the patients died, on the eighth and tenth days respectively, and small cakes of solid sulphadiazine were found in the recto-vesical fossa, surrounded by adhesions and lymph; histologically, there was little evidence of irritation specifically due to these lumps. It is concluded that the absorption of sulphadiazine is incomplete and that it is not the best compound for intraperitoneal use. Further investigations were planned but could not be carried out.

Table showing Amount of Various Sulphonamide Compounds in Urine and Blood following Insertion into Abdominal or Other Wounds

Preparation and Dose	Daily Excretion in Urine (g.)					Total Excretion (g.)	Concentration in Blood, free/total (mg. per 100 c cm.)			Remarks

Clinical Conclusions

In only a few cases was it possible to estimate the absorption and excretion of sulphonamides with accuracy, but clinical conclusions have been based on a series of more than 60 cases, many of which were air-raid casualties.

(A) *Local compared with General Administration.*—Local administration was found beneficial in every case. In 20 severe cases of lacerated wounds, including many multiple dirty bomb wounds, no case of gas gangrene or spreading wound infection developed. On the other hand, a clean through-and-through bomb wound of the leg, not involving bone, developed a virulent gas-gangrene infection two days after operation in spite of radical surgical excision, with drainage, and full doses of sulphapyridine administered prophylactically by mouth from the time of operation onwards. As regards abdominal operations, the cases recorded in the table showed uniformly satisfactory results so far as concerned the prevention of local infection, in spite of the fact that in many instances the peritoneum was heavily soiled. In one case a peptic ulcer re-perforated 4 days after the original operation for closure of the opening, and a second closure combined with gastro-enterostomy had to be done, yet no peritonitis developed. In other cases existing infection was suppressed. An appendix abscess was evacuated and packed with about 15 g. of sulphanilamide powder; a corrugated rubber drain was inserted and removed 24 hours later; the wound then healed by first intention. Ten weeks later the appendix was removed. No trace of the powder remained, the only sign of the abscess being a few light adhesions.

(B) *General Toxic Effects.*—The quantity of drug inserted rarely exceeded 10 g., and no general toxic effects of any significance were observed. The method is considered perfectly safe. If systemic administration was combined with local insertion, due allowance was made for the amount which had been inserted.

(C) *Local Effects other than Counteracting Infection.*—In muscle and fascial layers the sulphonamides appear to delay healing by their chemical effects on cell-proliferation and by their presence as foreign material. Their use should be reserved for contaminated or potentially contaminated wounds. Serous cavities showed no surface reactions of an inflammatory nature. As noted above, caked sulphadiazine was walled off by adhesions and a deposit of lymph, and it is considered that it was too insoluble to be entirely suitable. By packing sulphanilamide at one end of a nephrectomy wound and placing a tubular cigarette drain at the other, it was shown that the drug diffused throughout both the wound and the drain within 48 hours. This observation indicates that although most careful distribution over the whole wound is desirable, sulphanilamide will spread beyond the exact area into which it has been introduced.

Discussion

Many papers dealing with the intraperitoneal application of sulphonamides have now been published, the majority by American authors. Besides the workers mentioned in a recent review (*Lancet*, 1942, **1**, 235), experiments with animals have been described by Schmidt *et al.* (1941); Stevens, Taliaferro, and Haag (1941); Rosenburg and Wall (1941); Epps, Ley, and Howard (1942); Harvey, Meleney, and Rennie (1942); and Pearl and Rickles (1942). Some of these authors described results in human patients. Clinical observations have also been described by Burford and Graham (1941), Kinney (1941), Anderson (1942), and Hudson and Smith (1942). Ryan, Bauman, and Mulholland (1942) inserted sulphadiazine intraperitoneally during 6 operations, with satisfactory results.

Harild (1942), working with the Finnish Army, reports the intraperitoneal insertion of sulphathiazole into 8 cases of abdominal wounds, and recommends further trial. A detailed discussion during a meeting of American surgeons is given by Mueller and Thompson (1942), and Jackson and Coller (1942). General opinion is in favour of using sulphanilamide in doses of 5 to 10 g. per patient, in cases in which the peritoneum has been contaminated by bacteria; the suitability of sulphathiazole for this purpose is still under consideration. Several writers have stated that the insertion of sulphanilamide into clean wounds of the abdominal wall may cause sero-sanguineous effusions and therefore its application at this site should be restricted to infected cases. The researches described in the present paper were designed to compare the suitability of the various sulphonamide compounds for this purpose and to amplify results obtained in animal experiments (Fuller, Hawking, and Partridge, 1942). Although they are incomplete they support the use of these compounds in cases in which contamination of the peritoneal cavity has occurred. Sulphadiazine appears to be too slowly absorbed, and "hypoloid sulphanilamide L.S.F." to be too rapidly absorbed, for the optimal results to be obtained. A mixture of sulphanilamide and sulphathiazole might be the most satisfactory preparation.

Before leaving the subject, however, it is necessary to draw attention to the need for sterilizing compounds before their insertion into wounds: this has been emphasized by the recent case of tetanus which followed the intra-abdominal insertion of sulphapyridine during an abdominal operation (*Journal*, 1942, **2**, 134).

Summary

Sulphonamide compounds were placed in all types of wounds, including the peritoneal cavities of patients undergoing certain abdominal operations. The absorption was studied by estimating the subsequent concentrations in the blood and urine. The effects of this treatment seemed beneficial.

When sulphanilamide powder (5 to 10 g.) was inserted most of the absorption and excretion occurred in the first two days. When "hypoloid sulphanilamide L.S.F." (5 to 7.5 g.) was inserted most of the excretion occurred in the first 12 hours; when microcrystalline sulphadiazine was inserted some of it was still present in the peritoneal cavity 8 to 10 days later. It is considered that the absorption of "hypoloid sulphanilamide L.S.F." from the peritoneal cavity is too rapid, and that of sulphadiazine too slow, for the optimal therapeutic effect to be obtained.

We express our thanks to Prof. R. S. Pilcher for allowing us to make use of his 8 cases; and to many members of the junior surgical staff and of the nursing staff of St. Bartholomew's Hospital for their assistance at the operations and in the collection of the specimens of blood and urine.

A red pigment described as actinomycin A has been isolated in a pure crystalline organism, *Actinomyces antibioticus* (S. A. Waksman and M. Tishler, *J. biol. Chem.*, 1942, **142**, 519). Actinomycin is actively bacteriostatic and bactericidal in concentrations of 1 in 1,000,000 against certain Gram-positive bacteria. It is highly toxic to animals.

SPONTANEOUS ANNULAR DETACHMENT OF THE CERVIX DURING LABOUR

BY

M. DAVIES WESTERMAN, M.R.C.S.

This accident appears to be a rare complication of labour. DeCosta (1933) reported that there were only 32 recorded cases between 1820 and 1933, and the spontaneous nature of some of these was debatable. The following case can, however, be definitely included under the title given above. The last case published in the *Journal* was by Burt-White (1938).

Case History

The patient, a primipara aged 27, was a short, fat, flabby Jewess of excitable temperament who had attended the antenatal clinic regularly. She was always "full of woe," with multiple complaints but no abnormal physical signs, apart from oral sepsis. On routine vaginal examination (July 8, 1941) she was found to have a flat type of pelvis. The sacral promontory was felt. The foetal head remained high as she approached term, and she was booked for a trial labour in Shardeloes Emergency Maternity Hospital, Amersham. The expected date of delivery was Feb. 10, 1942.

First Stage of Labour.—The patient was admitted to hospital on Feb. 25, complaining of generalized abdominal pains and diarrhoea for 24 hours; there were no signs of labour having started. The head was two-thirds above the brim and freely movable; presentation V.R.O.P. The blood pressure was 150/100. At 10.15 p.m. on Feb. 26 her membranes ruptured, and she began having short pains every 5 to 10 minutes. After 10 hours the head was in the pelvis, and on vaginal examination the cervix was two-fingers dilated. The first stage continued normally, apart from difficulties arising out of her very unco-operative behaviour, until the evening of Feb. 27, when the pulse rate began to rise gradually from 88 to 110. Morphine 1/4 grain was given, and despite a good night the pulse had risen to 130 by the morning of the 28th. This rate was maintained till after delivery. The rhythm was always regular and the volume good, except for a short period (3 to 8 minutes) during the afternoon of the 28th, when it became irregular and thready. No cause for this rise could be found. Her general condition was good, and she was more co-operative. She was having fair pains every 5 to 10 minutes. There was no bleeding, the head was deeply engaged, and the uterus was relaxing well The following treatment was given during the first stage:

Feb. 26: Routine ol. ric.; bath; enema.
Feb. 27: 2.45 a.m, morphine gr. 1/4; 2 p.m., syrup. chloral gr. 30, pot. brom. gr. 30, tinct. opii m. 20; 11 p.m., catheterized. morphine gr. 1/4.
Feb. 28: 2 p.m., enema, pot. brom. and chloral gr. 30 āā.

Second Stage.—At 5.30 p.m. on Feb. 28 the patient began to "bear down," and the head appeared at the vulva. She was transferred to the labour ward, having poor pains at 15-minute intervals. The head did not appear again until 6.30 p.m., and showed no advance by 7.30 p.m. The general condition was good; the pulse rate was still 130 and of good volume. The foetal heart rate was 132. It was decided to terminate with forceps. She was anaesthetized with gas-and-oxygen and ether. The head was found well down, arrested in the transverse diameter. There was a small caput. The head was rotated; during this manœuvre a loose band of oedematous tissue was felt between the head and the sacrum. On further investigation this proved to be the prolapsed anterior cervical lip; the cervix having sloughed round the anterior two-thirds of its circumference, the head was presenting through the "rent." There were multiple loops of cord round the child's neck, which were pulsating slowly. As the "vital" part of the cervix had already separated, only the posterior third being left attached, it was considered that the danger of haemorrhage from the uterine arteries, and tearing into the vaginal vaults, was now over. Forceps were therefore applied to the head, through the rent, above the ring of detached cervix. The 8-lb. baby was easily delivered, but unfortunately it was stillborn. The cervix was delivered in front of the head, the posterior third evidently tearing off when traction was applied to the head.

Third Stage.—The placenta was expressed in 10 minutes. At no time during labour or delivery was there any abnormal or excessive bleeding. A careful examination was made both by hand and with the speculum, and a small tear in the left vaginal vault was sutured with No. 3 catgut. After delivery the patient was suffering from shock; her pulse was thready—rate 140—but the blood pressure was 110/80. She responded well to ordinary restorative measures.

The puerperium was uneventful. She got up on the twelfth day and went home 2 days later.

Post-natal Vaginal Examination.—The smooth regular cervical stump was palpated. It felt very like a normal short post-natal cervix. A speculum examination was not performed, as the patient would not co-operate. To all appearances the pain of this examination was as great as that experienced at any time during labour. The detached portion of the cervix was sent to the museum of the Royal College of Obstetricians and Gynaecologists. It was shaped like a quoit or a pineapple ring 3½ to 4 inches in diameter, with the centrally placed external os about two-fingers dilated. The anterior two-thirds was purple and oedematous, the posterior third pink and thin.

Commentary

Looking back on the case it is considered that the rising pulse rate was caused by the "shock" attendant on the detachment of the cervix, but it is surprising that the pulse volume and general condition of the patient were consistently so good. Had the nature of the condition been recognized earlier, would interference have been indicated or justifiable? It is probable that a live baby would so have been obtained; though an explanation for the stillbirth has not been found. As for the mother, it is hoped that, after the good termination, she will become pregnant again and have a normal labour, as was the end-result of the case reported by Epstein (1941). I should add that the maternal and foetal mortality rates in recorded cases of this complication are very high.

I wish to thank Dr. G. W. H. Townsend, medical officer of health for Buckinghamshire, and Miss Beatrice Turner, obstetrician in charge of Shardeloes Emergency Maternity Hospital, for permission to publish this case.

Medical Memoranda

Riboflavin Deficiency: With a Case Report

Thiamin, nicotinic acid, and riboflavin are the three main factors in the vitamin B complex. They are necessary for the formation of coenzymes concerned in carbohydrate metabolism and are closely related. A deficiency in any one affects the function of the other two. Riboflavin forms a phosphoric acid ester which combines with protein to produce the yellow oxidation enzyme of Warburg and Christian, an essential part of one of the oxidation-reduction systems of the body, associated with respiration and other basic cell functions. The most readily available sources are liver, muscle meats, cheese, yeast, and most green vegetables. The physiology of the absorption, storage, and excretion of riboflavin is not clearly known. The optimum daily requirement for adults is estimated at 1 to 2 mg.

Ill-health caused by lack of a single food factor is uncommon. One syndrome may predominate, but search generally reveals other deficiencies. It is especially noticeable in hypovitaminosis of the B group, many cases of pellagra presenting signs of ariboflavinosis. Sebrell and Butler (1938) showed that certain characteristic lesions, thought to be part of the pellagra symptom-complex, were due to riboflavin deficiency. Sydenstricker (1941) suggests that beriberi, pellagra, and endemic ariboflavinosis are major syndromes of B group avitaminosis resulting from prolonged subtotal deficiency of the whole B complex.

The syndrome of riboflavin deficiency (Sebrell and Butler) consists of angular stomatitis, tongue changes, corneal vascularization and other eye changes, seborrhoeic dermatitis, and general debility. Few instances of the condition have been described, and of these some lack definition.

CASE REPORT

A farmer's widow aged 75 had been in "poor health" for eight or nine years. Two years ago she came under my care, complaining of digestive disturbances, weakness, "neuritis" pains, failing sight, and inflamed eyes. She was emaciated and had many small punctate haemorrhages under the skin of the arms and legs. The heart was weak and fast, and the blood pressure 110/60. There was some anaemia (Hb 9 g.). The eyes showed marked chronic inflammation of conjunctiva and margins of lids, with constant copious purulent exudation. There were early cataracts in both lenses and marked photophobia. Conjunctival vessels in the palpebral aperture were dilated. Deep, raw, and slightly painful fissures persisted for years, and extended from the corners of the mouth for about an inch. Her tongue was swollen, sore, and fissured. Patellar and ankle reflexes were diminished. She was treated with improved diet, large quantities of thiamin, halibut-liver oil, and vitamin C (redoxon). She improved considerably, but the eyes, the angular stomatitis, and the sore mouth were not helped. In the spring of 1941 she relapsed and had severe continuous diarrhoea, associated with dermatitis of the legs and again a sore tongue. Nicotinic acid cleared up the diarrhoea and dermatitis but not the tongue. Eye symptoms were not improved. Her case was described in a paper on pellagra (Deeny, 1942). This spring she became weak and debilitated and lost weight. Her eyes were still affected as described above, and a few tiny leashes of capillaries had invaded the subepithelial region of the cornea. Photophobia was especially marked. The tongue was pale, flabby, clean, moist, burning, and sore, with several deep fissures and enlarged and flattened papillae. Two deep fissures ran from the corners of the mouth, both over an inch in length, with granulating surfaces. The nose and the neighbouring cheek surfaces showed follicular hyperkeratosis, giving a swollen "doughy" appearance. The lips were redder than normal and the line of junction of the mucous membrane and skin was irregular. Nicotinic acid was given without result, and later a 2-mg. injection of riboflavin (B. W. & Co.) three times a week for three weeks, followed by 4 mg. of riboflavin daily in 1-mg. tablets (Roche). In four weeks the angular stomatitis was healed, the eyes were no longer inflamed, the photophobia had gone, and the general health was improved. Her sight remained unchanged. Dr. V. P. Sydenstricker, who saw the case later, suggested large doses of riboflavin (12 mg. daily for two weeks) in the hope that the cataract might improve, but without result.

COMMENT

A feature of interest is that, while the patient suffered from a multiple deficiency, the syndrome of ariboflavinosis was present from the beginning, was unaffected by any treatment, and cleared up only when riboflavin was given. In some cases I have seen bluish patches on the tongue, usually near the margin, contrasting with the colour of the surrounding tissues, disappear with riboflavin treatment. In Northern Ireland riboflavin deficiency is fairly prevalent among elderly persons living on a poor diet. When it occurs in young persons it does not seem to be related so closely to diet, but more to lack of sleep or overwork, or as a complication of illness. I have found "poor" general health an important feature of the syndrome.

I wish to thank the Medical Research Council of Ireland; Dr. Sydenstricker; and Burroughs Wellcome and Co. and Roche Products, Ltd., for their generous gifts of riboflavin.

Convulsions under Trilene Anaesthesia

This case of convulsions occurring under trilene anaesthesia is of interest not only because I can find no other case reported in the recent literature on trilene, but because several of the factors usually seen when convulsions occur under anaesthesia are absent.

CASE RECORD

The patient was a pale nervous youth aged 17, and the operation to be performed was for cure of a right hydrocele. Routine examination of the chest revealed no abnormality. He had undergone two operations previously—one for an acute mastoid when 3 years old, following which he had pneumonia; the second for hernia when he was 12. There was no history of epilepsy.

The premedication given was omnopon gr. 1/3 and scopolamine gr. 1/300 one hour before operation; 0.5 g. of hexobarbitone was given intravenously, followed by nitrous oxide, oxygen, and trilene (using a Boyle's apparatus with the trilene in the chloroform bottle). No carbon dioxide was used Anaesthesia was smooth and the patient's colour good; about 18% oxygen was given most of the time. No pulse irregularity was noticed, and the respiration rate was slightly raised. Twenty minutes after induction had started, and with the patient in the first plane of third-stage anaesthesia, dissection of the hydrocele sac was proceeding when the respirations rather abruptly became irregular and shallow, then ceased No twitching of the face was noticed, but contraction of the neck muscles was felt at the same time. The patient became cyanosed, and clonic convulsions supervened, involving the whole body, so that the patient had to be held down on the table. These continued for about one minute. The anaesthetic was discontinued immediately and oxygen and carbon dioxide were administered, with rhythmic pressure on the bag, as, although the airway was clear, there was complete cessation of respiration. The pulse remained regular throughout, though the rate increased during the convulsions. The latter ceased, the patient's colour improved, and respiration recommenced in about three minutes. The operation was concluded under nitrous oxide and oxygen with no recurrence of the fits. The patient's condition seemed satisfactory on leaving the theatre, but he became cyanosed on return to the ward, where he was given oxygen intranasally. His recovery since then has been normal, and his condition now (a week later) is satisfactory. Morning and evening temperatures on the day of operation, and also the temperature taken immediately after the operation was completed, were normal. The temperature of the theatre was 74°.

The patient was never deeper than the first plane of anaesthesia, and only about 2 drachms of trilene was employed. This was taken from a newly opened bottle, some of which had already been used on other patients without ill effects

COMMENT

If it may be assumed that convulsions occurring under anaesthesia are not specific to any particular anaesthetic, then this case is unusual in that pyrexia and infection, which so often are predisposing conditions, were absent. Another point to note is that no atropine had been given, and only a small dose of scopolamine. Barbiturates and possibly morphine are regarded as inhibiting factors, and the patient had been given both. The airway was clear and there was no element of anoxia up to the onset of muscular contractions. I do not think that the sensory stimuli being produced at the time of onset were strong enough to initiate the convulsions. It has been suggested that convulsions can be caused by carbon dioxide imbalance, and it seems possible that in this case the slight hyperpnoea caused by the trilene may have resulted in a low alveolar concentration of carbon dioxide, following which came the period of apnoea with spasms. In favour of this was the speedy recovery when carbon dioxide with oxygen was administered.

Adder Bite

In view of the renewed interest taken in adder bite in Great Britain the following case may be worthy of record.

A W.A.A.F. patient aged 23 was admitted at 3.15 p.m. on July 6, 1942, to the medical department of the Newcastle General Hospital under the care of Prof. Hume. She gave a history of having been bitten by an adder in the region of the left internal malleolus at 4.30 p.m. the day before. A few minutes after the bite she noticed a swelling of her tongue and some difficulty in swallowing, swelling of the eyelids, and a gradually increasing swelling of the left leg. The swelling of the tongue lasted three hours, that of the eyelids five hours. She vomited a few times and had some abdominal pain at midnight.

On admission her general condition was good. There was a slight pyrexia of 99° F. The left leg showed a marked swelling up to the inguinal region. The skin temperature of the swollen leg was increased, and there was an erythematous rash on the medial side of the calf extending to the knee-joint. Two minute marks of fangs were seen in the region of the internal malleolus, and according to the patient these marks corresponded to the seat of the snake bite. No other abnormalities were found. The patient had complete bed-rest and no other treatment. The temperature returned to normal next day, and the swelling of the leg gradually subsided. In about two weeks the oedema had completely disappeared and the patient was allowed to get up. After three weeks she was discharged from the hospital, the bitten limb being normal in every respect.

I would like to take the opportunity of raising the question of serum treatment of adder bite. Is there any specific or satisfactory polyvalent serum against adder bite in Great Britain, and, if so, is the serum to be administered in every instance? In our case, though the patient's general condition was not much affected, there were pronounced toxic (allergic) signs, which cleared up spontaneously within two weeks.

I wish to express my thanks to Prof. Hume for his help and suggestions, and to Dr. J A. Charles, medical officer of health, Newcastle-upon-Tyne, and Dr. G. P. Harlan, medical superintendent of the Newcastle General Hospital, for permission to publish this case.

PAUL SZEKELY, M.D.,
Medical Registrar, Newcastle General Hospital

Reviews

EVOLUTION

Evolution: The Modern Synthesis. By Julian Huxley, M A., D Sc, F R S (Pp. 645 25s.) London: George Allen and Unwin. 1942.

A book on evolution may be concerned with whether it happened, what happened, and how and why it happened, whilst a preface by Shaw on the subject describes how it ought to have happened. Huxley's book is mainly concerned with how and why. He is certainly better equipped than any other British zoologist to answer these questions, for he has made personal contributions to genetics and natural history which allow him to write with authority on both topics, and has discovered quantitative laws of growth which apply both in the development of the individual and the evolution of species. His knowledge of the literature is most impressive; indeed, no writer on the subject since Darwin has produced such a body of facts from different sources in support of his standpoint.

Huxley is a Darwinist in the sense that he believes that the main trends of evolution were determined by natural selection, and not by inheritance of the effects of use and disuse, by an inner urge, or by supernatural guidance. And he holds that the steps have generally been small. But he admits that some species have arisen by sudden leaps, and that the evolutionary paths possible for a species are more limited than Darwin seems to have thought, among other things by the gene mutations available.

A large part of the book deals with the different ways in which species may originate. Where the barrier is spatial—for example, a mountain range—they may hybridize readily on meeting. Where it is one of habit—for example, a difference of flowering time or mating instincts—the hybrids may be quite fertile when formed. But, especially in higher plants, a reorganization of the nucleus may give fairly complete intersterility in a single step.

Medical readers will perhaps be disappointed that Huxley has not dealt in more detail with man. A good deal of human mortality is selective, apparently against predisposition to disease. And since men began to acquire skill with their right hands, human evolution has probably centred round the development of the left cerebral cortex. However, he deals vigorously with the fallacy which one still finds in some medical writings, that natural selection necessarily makes for progress. This is particularly far from the truth in a dominant species such as man, whose members, as a result of selection, may become better equipped for overcoming one another, and worse so for overcoming their environment.

In spite of this every reader who has kept an interest in zoology, and particularly in natural history, will find *Evolution* a unique storehouse of information; and for many years to come it will be absolutely indispensable for any serious study of the questions with which it deals.

J. B. S. HALDANE.

SUBACUTE BACTERIAL ENDOCARDITIS

Subacute Bacterial Endocarditis. By Emanuel Libman, M D., and Charles K. Friedberg Reprinted from Oxford Loose-Leaf Medicine. (Pp 108 15s) London, New York, Toronto. Oxford University Press 1942.

While the new chemotherapeutic agents have given striking results in the treatment of certain infections, bacterial endocarditis remains one of those which are usually uninfluenced by these drugs. Drs. E. Libman and C. K. Friedberg have written this monograph on subacute bacterial endocarditis in the hope that wider knowledge of the malady may lead to earlier diagnosis and more successful treatment. Among predisposing factors are mentioned previous valvular disease or defects, physical and mental strain, influenzal infection, operative procedures (notably dental extractions), and pregnancy and the puerperium. The section on symptomatology contains a useful survey of skin lesions, including petechiae, subungual splinter haemorrhages, Osler lesions (which are attributed to arteriolitis rather than embolism), and the less common Janeway lesions.

That subacute bacterial endocarditis may develop in many guises is shown by the authors' list of syndromes, in which the disease is demonstrated as simulating influenza, pulmonary tuberculosis, rheumatic fever, typhoid fever, malaria, myocardial failure, hepatic or subphrenic lesions, reno-vesical disorders, gastric carcinoma, acute appendicitis, and cerebral lesions. One of the most important sections of the work is that devoted to the "bacteria-free" stage of the disease: in this phase the patient is afebrile, the skin lesions are infrequent, the anaemia persists, but a leucopenia may replace the usual leucocytosis. Sternal tenderness is mentioned more than once by the authors, but most clinicians who have sought help from this sign will probably agree that it is an uncommon phenomenon. It is not surprising that Drs. Libman and Friedberg take a poor view of prognosis; it is even perhaps remarkable that they put the spontaneous recovery rate as high as 3%. This is an important monograph on a dramatic but depressing disease.

SIR WILLIAM WILDE

Victorian Doctor. Being the Life of Sir William Wilde. By T. G. Wilson, M.B., Litt.D., F.R.C.S.I. (Pp. 338. 15s.) London: Methuen and Co.

To most of those few who remember him at all the name of Sir William Wilde is merely that of "Oscar Wilde's father." Yet the reader of Dr. T. G. Wilson's *Victorian Doctor* will readily admit that William Wilde deserves a biography in his own right—far more, indeed, than his much-publicized and unhappy son. His biographer claims for him that it was he who first put aural surgery on a scientific basis. Certainly he was the leading aurist and ophthalmologist of his day, and his hospital, St. Mark's, for years the pioneer on aural teaching in these islands. Famous throughout Europe, in Dublin he was a legendary figure, and society flocked to the house in Merrion Square where Sir William and his no less remarkable lady entertained. His greatness was not confined to surgery: he had travelled far and read widely, and he made important contributions to Irish archaeology. His last years were a period of decline, for the notorious Travers case marred his zenith. He gave less time to surgery and more to archaeology and his beloved Connaught. He died at sixty, eccentric and embittered, a quaint figure, jeered at by the children of the streets. To-day this is the only period that is remembered, even in Ireland which he served so well, and Dr. Wilson's biography is a service not only to his memory but to the history of medicine.

Wilde's was a full life, and he lived it in an age of change. Born in the year of Waterloo, he was a student in the days of body-snatching, worked in the horrors of the famine years, and lived to see the birth of antiseptic surgery. The years of his prime were the heyday of Dublin medicine, and the background of Dr. Wilson's story is richly laced with the great figures of Stokes, Graves, Colles, Crampton, and Corrigan, men whose fame has lived where Wilde's has faded. These, with the picture of the Ireland of his day, give the central figure its perspective. Nor does he lose stature by their proximity. Brilliant, imaginative, and active, entirely human in his virtues and in his vices, William Wilde has real greatness, and Dr. Wilson's admirable and delightfully written biography does him but justice.

TUBERCULOSIS IN CHILDHOOD

Tuberculosis in Childhood By Dorothy Stopford Price, M.D. With a chapter on Tuberculous Orthopaedic Lesions, and other contributions, by Henry F. MacAuley, M.Ch., F.R.C.S.I. (Pp. 215; 87 illustrations. 17s. 6d.) Bristol: John Wright and Sons, Ltd 1942.

It is still too common a belief that primary tuberculosis in childhood is an infection acquired and overcome by every child, with minimal, if any, disturbance of health and without significant sequelae. Occasionally we even hear the opinion expressed that such an infection is a "good thing," since by its means immunity is acquired to tuberculous disease later in life. Dr. Dorothy Price firmly, and quite rightly, believes that "many vague symptoms of ill-health besides actual disease" can be attributed to the tubercle bacillus, and that primary tuberculosis is of great importance not only because it can be immediately fatal but because it may give rise to various forms of the disease which cause severe ill-health and may prove fatal later. Dr. Price not unjustly expresses a strong opinion that too little attention is paid to this subject in this country, and therefore her book "is intended to be a brief practical guide to the diagnosis and treatment of tuberculosis in children." Now there can be no doubt that Dr. Price has read widely the relevant literature and has herself had ample material on which to base a personal study. But, judged by the standard the author herself has set, the book is not likely to achieve its purpose. In spite of its format, it is not brief (there is much repetition) nor is it written as a "guide" should be: indeed, the reader seeking guidance for everyday practice may often be confused. The pathological background of tuberculosis is not simple, and cannot be simplified by a rigid use of the three-stage classification, which is forced on the reader on almost every page. Even more unfortunate is Dr. Price's insistence on immunological associations with the three stages, which themselves have little practical meaning in connexion with tuberculosis in childhood. There are other grounds for criticism. Thus the author states: "The foci which initiate tertiary phthisis show a marked tendency to caseation in contrast with the focus of primary tuberculosis." Clearly for "caseation" we must read "liquefaction." The following speaks for itself: "When a child is known to have passed successfully through a primary tuberculous infection and then dies some years later of tuberculous meningitis, the state of affairs is rather different from acute meningitis. These cases are uncommon; they are usually the result of a fall or blow on the head." Dr. Price revives mediastinal gland tuberculosis as "a clinical entity in which the primary lung focus is closed, but the tuberculous process in the mediastinal glands remains active." She has an unjustified belief in the value of the Hamburger ointment test and in the conclusions to be drawn from its sole use. Finally, one would need much more than the figures given by the author to convince us that "if all pulmonary cases were diagnosed during primary infection, and treatment instituted, there would be complete cure in very nearly 100 per cent."

In spite of the severe criticisms expressed, we would advise paediatricians and tuberculosis workers to read the book, not only because it contains useful and important matter, but also because it is based on a point of view fundamentally different from that current in this country.

Notes on Books

Food and Beverage Analyses, by Dr. M. A. BRIDGES and Miss M. MATTICE (2nd edition, Henry Kimpton, 20s.), provides readily accessible information on all that may be asked regarding the contents of articles of food and drink. The information covers nutritive and calorific values, quoting the percentages of carbohydrate, protein, and fat, and indicating the intake usually practised for each article. It also gives tables showing the proportions of all the mineral constituents contained in them and their values in terms of the several vitamins. The range of information is very extensive; hardly any article of diet is omitted. A general discussion of dietetic requirements and the function of vitamins completes a very useful volume.

Dr. A. H. DOUTHWAITE has again edited *Hale-White's Materia Medica, Pharmacy, Pharmacology and Therapeutics* for its 25th edition (J. and A. Churchill, 14s.). This incorporates 71 additions to the *British Pharmacopoeia* that have appeared in the official addenda. In spite of extensive additions the size of the book has shrunk without any loss of legibility. Near the index is a list of drugs which must not be prescribed during wartime or in which strict economy should be exercised by reason of their scarceness. The parts of the volume most thoroughly revised for this edition include the chapter on sulphonamides, which has been rewritten and expanded; and Dr. P. M. F. Bishop has revised his contributions on the subject of the sex hormones. Sir William Hale-White must look with pride upon this evergreen manual which he first gave to the medical profession fifty years ago—one of the good things that came from Guy's and have remained "in the family."

The calendar of the Royal College of Surgeons of England for 1942 (Taylor and Francis, Ltd., Red Lion Court, Fleet Street, 2s. 6d.) is even smaller than its predecessor, having 200 pages compared with 226 pages for 1941. Before the shortage of paper began to become progressively more acute the pages numbered well over 600. All the current official information is given, and the register of Fellows in alphabetical order, with their addresses, has reappeared, taking the place of the regulations for the diplomas and the licence in dental surgery. The Roll of Honour is now nearly twice as long as in 1941.

ACTIVITY IN REHABILITATION

BY

Sir ROBERT STANTON WOODS, M.D., F.R.C.P.
Consultant Adviser in Physical Medicine; Member of the Committee on Rehabilitation, E.M.S., Ministry of Health

When a member of the rescue squad gingerly removes the debris from the limbs of the entombed air-raid victim, or a stretcher-bearer picks up the wounded soldier, he takes the first step in a long series of activities destined to rehabilitate or restore to health the casualty he has rescued. Every phase of the patient's subsequent treatment—first-aid, resuscitation, operation, blood transfusion, skin-grafting, physiotherapy, psychotherapy, supervised exercises, occupational therapy, vocational training—is part of a well-ordered plan with one object in view: that of returning the injured person to the fullest possible living and working capacity.

Such a plan, whereby the industrial or war casualty is followed through from the injury to his return to work, is fundamental in the organization of the Emergency Medical Service. At no period has the pronouncement "The operation was successful but the patient died" ever been more than a popular gibe. Paraphrased, however, as "the fracture was successfully set but the limb completely useless," it becomes relevant to what not seldom occurred in the recent past when the unfortunate victims of injury were sent out into the world with the not unfamiliar rigid joints, the wasted claw-like hands; so that, encountering them, one was at times forced to the conclusion how much better a really good artificial limb would have been.

Early Application of Physical Measures

With the extension of modern rehabilitation facilities came the widespread realization that physical measures for restoring function—massage, electrical stimulation, remedial movement—must, to be effective, be applied early, in many cases from the beginning of treatment. The fracture case is no longer merely a broken bone to be joined together in good alignment, but a bone clothed in muscles, whose blood and nerve supply must be maintained throughout in the face of enforced immobilization, and in which healing must keep pace with the bony union. Massage, electrotherapy, assisted movement, afford very necessary and very effective means for maintaining the ebb and flow of blood and lymph in a muscle which must not or cannot be moved by the patient himself.

But as soon as the patient *can* move the injured part with safety, such purely local and passive measures of restoration may in the majority of cases be abandoned with advantage in favour of active therapy, since the muscle stimulus most potent for good is the one coming from the central nervous system. As the patient's muscles contract in voluntary effort they promote the blood and lymph flow and bring fresh supplies of nutrient fluid to the injured tissues by a much more physiological mechanism than that of artificial stimulation. Furthermore, these nutrient fluids bathing the injured area must possess certain biochemical properties if optimum healing is to occur. Thus the health and general muscle tone of the patient have to be considered, the scope of rehabilitation is widened still further to include dietetics and general exercise, and we are no longer dealing with an injury but with an injured body.

Quite apart from the economic fear, the dread of losing one's job, of having to be kept by relations or by the State, even the merely temporary loss of use in an arm or leg can be accompanied by serious mental depression peculiarly inherent in this type of illness, since movement, one of the fundamental attributes of living matter, is as natural and necessary as breathing and eating. The patient becomes convinced that he is crippled, paralysed; he will never be any good again. Once the disabled person can be shown that he can throw a dart or kick a football or hammer in a nail or work a loom almost as well as the next patient and certainly better than he himself did yesterday, he is on the road to recovery, mental as well as physical. And now we are no longer dealing with an injured body, but with an injured person—body, mind, spirit.

Purposeful Movements of Muscle Groups

Even stereotyped voluntary movements of the injured part alone, since they demand the patient's co-operation and introduce the element of self-help, are excellent psychologically. Of far greater therapeutic value are purposeful and productive movements of groups of muscles such as those required in the performance of games and handicrafts, or the resumption of Army training, where the creative and competitive instincts can be brought into action and the patient's attention is no longer focused on his disability but rather on his returning skill in achievement. It is better still when he can actually forget himself in the interest and usefulness of the work or the sheer enjoyment of the game so that muscular co-ordination is achieved automatically and without conscious effort.

The importance of activity in recovery is not confined to injuries. Before and after an abdominal operation, before and after childbirth, in recovery from many illnesses, and very especially in the treatment of the psychoneuroses, active and productive exercise now plays a prominent part in treatment. In a certain Army convalescent depot of 1,000 beds, as at present constituted, 25% of those undergoing active rehabilitation come under the category of "hernia."

Medical Supervision

All these therapeutic measures ought to be under the direct supervision of an instructed medical practitioner, whilst the patients are guided at their work and play by a staff of male and female medical gymnasts and occupational therapists. In this way only such movements as are safe and effective in any given case are performed, and the range of activity is gradually increased with the patient's increasing capacity.

Planned at first to deal with air-raid victims only, the E.M.S. later afforded accommodation for Service casualties, and later still its orthopaedic and fracture centres have become extended and will co-operate in the ambitious scheme for industrial rehabilitation now on foot. It would seem that the demands of such an elaborate and growing organization for trained masseuses must become for a time increasingly difficult to meet. Fortunately, however, the problem is being partly solved by the more widespread use of active than of passive physical treatment. Not only does the patient benefit mentally and physically, as we have seen, by the increasing use of active rehabilitation, but whereas in the past a masseuse might spend three-quarters of an hour giving passive treatment (massage and electrotherapy) to one patient, or could treat at the most only two patients simultaneously, she can now give active treatment in medical gymnastics to eight or nine patients at the same time. Passive therapy still has an important place in rehabilitation, but as soon as the injured part can be used at all the physician or surgeon in control makes his decision as to how far active therapy can be substituted. The earlier this can safely be brought about the more rapid the patient's recovery and the greater the saving in trained personnel.

MEDICAL SICKNESS AND LIFE ASSURANCE

The annual meeting of the Medical Sickness, Annuity and Life Assurance Society, Ltd. (whose registered offices are now at Highfield, Chesterton, Cirencester), was held in London, with Mr. R. J. McNeill Love, chairman of the Board of Directors, presiding. Reference was made to the heavy personal losses the Society has suffered during the year in the death of its chairmen, Dr. F. C. Martley and Dr. G. de Bec Turtle, and of Sir William Willcox, who had been a member of the Board for more than twenty years.

The chairman said that the amount of new business in the Life Assurance Fund was only slightly smaller, but the claims by death had been lighter and the surrenders fewer. On the Sickness Fund the claims had been considerably lighter and the premiums were up a little. The funds of the Society had been increased by £173,537, and now stood at £2,355,319. The quinquennial valuation had taken place at the end of the year under review, and on a cautious estimate a surplus of nearly £83,000 was disclosed on the Life Assurance and Annuity Fund and of £120,850 on the Sickness Fund. Both Funds had been strengthened and provision made for all known contingencies.

A vote of thanks was accorded to the staff on the motion of the chairman, who mentioned that Mr. Bertram Sutton, the manager and secretary and now one of the directors, had been with the Society for 43 years, 30 of which had been in the capacity of chief officer.

CONTROL OF VENEREAL DISEASE

The use of compulsory measures for the control of venereal disease has been debated often enough, and now, under Defence Regulation 33B, powers are made available to apply compulsion in certain carefully defined circumstances. As a statement from the Ministry of Health published at p. 616 makes clear, this limited compulsion leaves the voluntary basis unchanged. In brief, the regulation provides that persons named by two separate patients as the suspected source of infection can be required by the M.O.H. of the county or county borough in which they live to attend for examination and, if necessary, for treatment by a special practitioner.

It may be recalled that when in 1928 the Edinburgh Corporation introduced a Bill which, following the Swedish model, was among other things to authorize the M.O.H. to serve a notice on defaulters to complete treatment until certified cured, it was defeated in the House of Commons by 156 votes to 93. In 1923 the Trevethin Committee concluded that legislation was impracticable and inadvisable. In 1937 the Minister of Health sent a commission of experts to study the conditions in Holland and the Scandinavian countries.[1] The commission doubted whether compulsion was justifiable in view of their conclusion that in Holland and this country voluntary measures of treating venereal disease "have been almost equally successful" in controlling these diseases as in the Scandinavian countries. This conclusion has been challenged.

Defence Regulation 33B once more opens the question of compulsory notification and treatment of diseases which, however small in extent in peacetime, nevertheless constitute a serious public health and social problem. It is well, therefore, to consider briefly the arguments for and against, so that the medical profession and through it the public may have their minds clear on the subject. The success of the voluntary basis of treatment must in the long run rest upon fully informed medical and lay opinion, and upon a healthy attitude of mind towards sex and diseases which in the main arise from promiscuous sexual intercourse. As Dr. Margaret Rorke pointed out in this *Journal*,[2] "There is not the same sense of shame and necessity for secrecy as regards venereal disease in Scandinavia as still exists in England." The Scandinavian peoples seem to have a more matter-of-fact attitude towards sex—a public health official in one large Scandinavian city strongly advocated the supply of contraceptives through automatic machines. Sir Wilson Jameson, the Chief Medical Officer to the Ministry of Health, performed a great service when he broke the V.D. taboo in a broadcast given at the end of last month, and struck the right note when he invited the public to look upon venereal diseases in the same way as a doctor did, regarding them as presenting the same sort of problems as other infectious diseases. He decried the hush-hush attitude that prevails in a country where puritanism and hypocrisy are at times not easily distinguishable from each other. This broadcast, with the official background behind it, was an important step towards that enlightenment which is essential if voluntary measures are to succeed in controlling venereal infections. In the past the British Social Hygiene Council has battled manfully with this problem, but the success of its propaganda efforts was rather sharply challenged by Col. L. W. Harrison at a meeting of the Medical Society for the Study of Venereal Disease in March of this year.[3] He criticized county councils and county borough councils for a lack of zeal in acting upon propagandist advice issued by the Ministry of Health, and at conferences early in 1939 with medical officers of health and venereal disease officers he found no great enthusiasm for the use of lectures and films as a means of instructing the public. Numbers attending courses of instruction, lectures, exhibitions, and film shows organized by the British Social Hygiene Council during the ten years 1930–40 were analysed by Dr. Hartley of Scientific Computing Services, Ltd., and this analysis, according to Col. Harrison, brings out that 944 persons in every 1,100 could not have attended a lecture or film show on the subject more than once in the ten years. He asks the question, "Could they [i.e., lectures and films] have made much more improvement than the posters displayed in the public lavatories?" Various speakers at the meeting did not share Col. Harrison's scepticism about lectures and films—and incidentally he made it clear that his remarks should not be considered as an attack on the B.S.H.C.

If we accept the view that propagandist efforts in the past have had very limited value, this does not imply that they will have as little value in the present and the future, but it may be that the time, energy, and money spent on such propaganda could be more fruitfully used for other purposes if notification and treatment of the disease were made compulsory. The case for compulsion was forcefully put by Major S. M. Laird[4] at a meeting of the Medical Society for the Study of Venereal Disease in April this year. An investigation in which he took part in 1937 showed that in various parts of Staffordshire 50% of cases of early syphilis and 30% of gonorrhoea defaulted. Sir Kingsley Wood, when Minister of Health, stated that the percentage of clinic patients in England who completed treatment and tests of cure was 12.9 in 1925 and 17.5 in 1935. Major Laird points out that the defaulter rate of England in 1935, at 82.5%, compares most unfavourably with the corresponding defaulter rate of 2.5% for Sweden. This and other comparable figures make it impossible for him to agree with the conclusion of the British commission in 1937 that "the degree of success in reducing the incidence of syphilis in the countries employing compulsory treatment and in those which rely on a voluntary system is broadly similar." After the discussion which followed Major Laird's paper, the Medical Society for the Study of Venereal Disease passed the following resolution with an overwhelming majority: "That in the opinion of this meeting . . . further powers, legislative and administrative, in the treatment and prevention of venereal diseases are required to deal with the sources of infection, contacts, and defaulters."

The arguments adduced by the British commission against compulsory measures were that they (1) may induce the infected to conceal the disease from fear of exposure, (2) are not easy to apply in such a densely populated country as this on account of the difficulty in tracing those who try to evade the law, (3) may open the way to blackmail, and (4) are not consonant with the British idea of the liberty of the subject. If we share Sir Wilson Jameson's view—as we must—that venereal infections present to medical men problems similar to those of other infections, then it would seem a little late in the day to talk about the liberty of the subject in this context. The medical profession and the public have accepted without demur the compulsory notification of small-pox, diphtheria, scarlet fever, whooping-cough, typhoid, and other infectious diseases. They raise no objection to a law which may inflict a penalty upon any person who, "(*a*) knowing he is suffering from a notifiable disease, exposes other persons to the risk of infection by his person or conduct in any street, public place, place of entertainment or assembly, club, hotel, inn, or shop, or, having the care of a person whom he knows to be so suffering, permits him to expose others to the risk of infection in any such places, or (*b*) knowing he is suffering from a notifiable disease, engages in any trade, business, or occupation which he cannot engage in without risk of spreading the disease."[5] Nor is any voice raised against the regulations which make it possible to remove to hospital any person suffering from a notifiable disease, "(*a*) if his circumstances are such that proper precautions cannot be, or are not being, taken to prevent spread of infection, and (*b*) that serious risk of infection is being caused to other persons."[6] There is no need to elaborate the argument which distinguishes licence from liberty, especially when it is a question of the liberty to pass on venereal disease. In considering the other objections to compulsion, we believe that it should not be difficult to make adequate safeguards against blackmail or the spread of misinformation through malice. It cannot be denied that compulsory measures are more easily enforced in less densely populated countries, such as Sweden, Norway, and Denmark, and in Great Britain the control of venereal disease in the ports must always be a difficult matter. Whether these difficulties would be greater or less with compulsion is an open question. The most formidable objection to compulsion is that it might carry with it a risk of driving the disease still further underground because of the fear of public exposure on the part of infected persons. But, provided adequate steps are taken to maintain the confidential relationship between patient and doctor, and provided venereal disease centres are made inconspicuous by, for example, their inclusion in institutions where other clinic work is carried out, the risk would appear to be minimal, and it would be the duty of public health authorities, by propaganda, to convince the infected that knowledge of their disability would be a private matter between them and the medical profession. Fortunately modern medicine can offer effective treatment for venereal diseases, and is, therefore, in a strong position to insist, if it wishes so to do, that infected persons should be treated and that such treatment should be carried to completion. If treatment were of little avail, then a suspicious public might accuse the medical profession of a wish to pry into its intimate affairs.

It should be made clear that the question of compulsory notification is not raised in Defence Regulation 33B, but this question will no doubt arise in time. When it does we can only hope that both doctor and public will discuss it in objective terms so that a reasoned conclusion may be arrived at. Meanwhile every possible step must be taken to stem the increase of venereal disease that has inevitably occurred in this war. So far official advice is rather like the well-known advice from *Punch* to those about to marry. We cannot, of course, expect that health authorities in this country would go so far as the Scandinavian public health official referred to above; as things are at present many believe that the issue of prophylactics is more likely to be successful in the prevention of venereal disease than the issue of moral and hygienic propaganda.

CAVERNOUS SINUS THROMBOSIS

Cavernous sinus thrombosis is a comparatively rare condition. Smith[1] in 1918 could collect only 300 cases from the literature. The majority are secondary to sepsis of the face and orbit and show the classical signs of chemosis, exophthalmos, and ocular palsies. A more chronic type with much less distinctive symptomatology occurs in association with ear disease. Aseptic thrombosis is also occasionally found as a terminal marantic event. Grove,[2] in a comprehensive review in 1936, concluded that the mortality of the anterior fulminating type was probably 100% and that the recovery rate of all types—traumatic, aseptic, and septic—was not greater than 7%. Several methods of surgical approach to the sinus have been described which aim at drainage and ligation of the venous channels. Grove found these methods more disappointing than when the original focus alone was treated surgically, the operation being combined with ligation of the common carotid as described by Eagleton.[3]

In the past few years there have been several reports of recovery with the use of drugs of the sulphonamide series. Seydell[4] and Barnshaw[5] have both reported cures with sulphanilamide. Barnshaw's patient was a child of 7 who had a bilateral infection after a stye on the eye. He used 10 c.cm. of prontosil 4-hourly for 6 doses and then sulphanilamide 10 grains four times a day for 4 days; in spite of the short course of treatment the child recovered completely. Morrison and Schindler[6] treated a boy of 5 years successfully with sulphapyridine; they gave a total of 63 grammes of the drug and maintained the blood concentration between 10.4 and 16.5 mg. per 100 c.cm. for 9 days. Wolfe and Wolfe[7] were the first to use sulphathiazole. Their patient was a boy of 17 who developed signs of thrombosis after a furuncle of the nose. He was first treated with small doses of sulphanilamide, but as soon as *Staph. aureus* was isolated from the blood stream sulphathiazole was substituted in doses of 2 grammes every 4 hours, maintaining a blood concentration between 10.0 and 17.6 mg. per 100 c.cm. The dose was reduced after 14 days and continued for another 15 days. Moore *et al*[8] also used sulphathiazole in very large doses, securing a blood concentration between 25 and 33 mg. per 100 c.cm. for 6 days. Their case was complicated by multiple embolic phenomena, but eventually, apart from some mental impairment, the patient recovered. The drug was continued in small doses for three months after the infection subsided.

Heparin has recently been combined with chemotherapy. Lyons[9] was the first to apply the treatment to this type of thrombosis. His object was to prevent extension of the thrombosis and dissemination of infected emboli. The heparin was given by continuous intravenous drip in amounts sufficient to maintain the blood coagulation time at approximately 90 minutes. Heparin treatment was kept up for 15 to 20 days, sulphathiazole being given concurrently in large doses and continued for some 3 to 4 months after the infection had subsided. Both the cases described developed pulmonary infarcts during treatment. Leroy Schall,[10] with the same method, had no haemorrhagic manifestations in his two cases. Erschler and Blaudill[11] were not so fortunate. Their patient, a girl of 22, developed sinus thrombosis after nasal furunculosis. Sulphathiazole and heparin were given and a blood concentration of 8.15 mg. of sulphathiazole per 100 c.cm. was maintained. On the second day of the heparin therapy the patient had haematuria, and by the ninth day she was passing clots of blood in the urine, and purpura, ecchymosis, and haemorrhages into the joints had appeared. Both forms of treatment were stopped for 36 hours, but as there was a recurrence of chills and fever the sulphathiazole was restarted and continued for 13 days. There was no recurrence of haemorrhage, and the patient made a complete recovery. *Staph. aureus* is the infecting organism in the majority of cases of cavernous sinus thrombosis, and therefore penicillin is the ideal remedy; at least one encouraging example of its use has been reported.[12] Until penicillin becomes available for general clinical use, sulphathiazole is the sulphonamide of choice. It should be given in large enough doses to obtain a blood concentration of about 10 mg. per 100 c.cm. during the acute stage, and it is probably wise to continue treatment in small doses for about 3 months after the original infection has subsided. From the few published cases it would appear that this drug has revolutionized the prognosis in cases of septic cavernous sinus thrombosis. While theoretically there is an indication for the use of an anticoagulant, there is no evidence that this gives more satisfactory results than when sulphathiazole is used alone, and any theoretical advantages are outweighed by the risk of severe haemorrhagic reactions.

CLINICAL IMPORT OF RECENT WORK ON VITAMIN A

From prolonged research on the influence of a shortage of vitamin A on the central and peripheral nervous systems, Sir Edward Mellanby has recently concluded that the degeneration observed is due to pressure exerted by the overgrowth of the bone contiguous with the affected tissues. In 1938[13] he showed that a dietary deficiency of vitamin A resulted in bony overgrowth of the periosteal layer of the labyrinthine capsule, especially of that part surrounding the internal modiolus. The dogs on which his experiment was made showed incoordinate movements of locomotion and evidence of deafness. The overgrowth of bone must press on and in some places touch the nerve, which seems to cause its degeneration. A similar hyperplasia was found in the neighbourhood of the optic and trigeminal nerves, and this may be the cause of the xerophthalmia associated with vitamin A deficiency.[14,15] In advanced stages of the deficiency serous labyrinthitis was found; this was cured by giving vitamin A, though the nerve degeneration was not. Substituting potatoes for the cereals in the diet greatly reduced the nerve degeneration. It was suggested that the small amount of carotene in the potatoes eaten was enough to account for their action or that the cereals had a toxic action which hastened the pathological changes in the absence of vitamin A. The deficiency produced more severe changes in the bones of young animals than of adults. Large reserves of vitamin A postponed the development of symptoms.

In 1941[16] Mellanby described more fully these bone changes affecting the nervous system. He concluded that a function of vitamin A is to limit the number and the degree of activity of osteoblasts and osteoclasts, a deficiency resulting in proliferation of cancellous at the expense of compact bone and causing many bones to lose their normally fine moulding and outline and to become thickened and enlarged. Overgrowth of the cranial bones may press on and produce deformity of parts of the brain. The greatest hypertrophy was found in the bones forming the posterior fossa of the skull, so that the medulla oblongata, pons, cerebellum, and nerves in close association with these parts of the brain are more particularly affected. The posterior root ganglia and the anterior root nerves of the spinal cord may also be squeezed and the nerve fibres destroyed by overgrowth of the vertebral bones. The bone overgrowth and degenerative changes in nerve are greatest in the cervical region of the cord. In advanced cases of this deficiency there is evidence of a substantial rise in intracranial pressure. The pressure of the cerebrospinal fluid in the cisterna magna may be double that of animals receiving similar diets containing vitamin A. Associated with these changes, the cisterna magna and the fourth ventricle are diminished in capacity, while a degree of internal hydrocephalus (expansion of the third and lateral ventricles) indicates increased pressure, probably transmitted from the posterior fossa.

LONDON'S BILL OF HEALTH FOR 1941

In the second full year of war London—by which is meant the county, with a population of 4 million or thereabouts—remained remarkably healthy.[1] Even the biennial rhythm of measles epidemics was broken. The expected outbreaks of contagious disease consequent upon shelter life did not materialize. Influenza, pneumonia, and bronchitis claimed fewer victims. Small-pox and typhus went unrecorded. Scarlet fever, which fifty years ago had a death-roll of four figures in London, was the cause of only 2 deaths in 1941. The deaths from diphtheria and whooping-cough rose slightly, but the totals remained small. Notifications of diphtheria multiplied by 4 compared with the year before, but even so the total was only 600, and the deaths in 1940 and 1941 together were fewer than in 1938. Pulmonary tuberculosis caused some disquiet by reason of an increase in notifications, but the number of deaths was down. Maternal mortality went back, unfortunately, to the higher rates of 8 or 9 years ago, and the infant death rate rose to the 1938 figure of 57 per 1,000 births; but even the 1938 figure was considered a low one at the time. Deaths from street accidents fell by one-third. The school medical service reported that of the children examined in four age groups 93.7% were of satisfactory nutrition, compared with 93.4% in the last pre-war year. Venereal disease clinics had fewer cases, but here, of course, it must be remembered that a large proportion of the population of the ages at which venereal disease is most likely to be acquired were no longer civilians. That illustrates one of the possible fallacies which underlie these cheerful statistics. The population of London has altered so much as a result of war conditions that there is no certain base-line from which to calculate percentage rates and make comparisons with normal years. Successive evacuations have taken place, but very many evacuees have returned. In the year under review the number of elementary school children in London in January was 85,000 and in December 150,000. The business and residential life of London has also been in part uprooted and again to some extent replanted. Nevertheless, after making all discounts, the resilience of London in health and spirit, despite aerial bombardment in the earlier months of 1941, transport difficulties all the time, black-out, restrictions on amenities, shortage of certain popular articles of food, and the strain and anxiety of war as well as its petty exasperations, is not merely a thing to wonder at but a subject worthy of the serious consideration of students of social science. The streak of heroism appears again and again in Dr. Allen Daley's routine record of health services. During the year 26 members of the staff of the health department lost their lives at the post of duty, and 95 were injured by enemy action. A woman medical officer and a man ambulance driver gained the George Medal, and awards and commendations for gallantry were made to 9 other members of the staff, 7 of them women. Special mention is made of the Council's midwives, who never left a call unanswered, and cheerfully carried out their duties in exacting circumstances, often delivering their patients while bombs were falling. The ambulance service manifested its usual initiative, pluck, and efficiency. As for the hospitals, if a hospital was partly or wholly put out of action patients and staff were promptly transferred elsewhere. The work of the health services was never disorganized.

RESUSCITATION FROM ASPHYXIA

In experiments on dogs G. L. Birnbaum and S. A. Thompson[1] of New York have pointed out that in advanced asphyxia—produced by inhalation of pure helium or nitrogen, or by tracheal obstruction—temporary resuscitation can be effected, after respiration has ceased and the circulation is rapidly failing, by rhythmic inflation of and suction on the lung with the inert gas (nitrogen or helium); this is termed asphyxial resuscitation, and as a result the animal may be kept alive for 1 to 3 minutes longer without oxygen or air. For this mechanical resuscitation they employed the Emerson resuscitator, which inflates the lungs to 14 mm. of mercury pressure and aspirates to -9 mm. The apparatus was usually regulated to make 16 to 20 complete excursions or respiratory strokes per minute and was connected with the face-mask or intratracheal tube. Birnbaum and Thompson find that the mechanism of this asphyxial resuscitation is primarily a reflex phenomenon which is initiated most efficiently by suck-and-blow resuscitation within safe limits of pressure. This temporary resuscitation with inert gas can be accomplished by suck and blow with the Emerson apparatus, arranged as described above, in 85% of instances, if the resuscitation is started within periods of 45 seconds to 2½ minutes after cessation of respiration. On the other hand, similar resuscitation with the inert gas can be accomplished in only 15% to 20% of instances by one of the following methods: manual artificial respiration with nitrogen inhalation, rhythmic pressure with nitrogen at $+12$ to 14 mm. Hg, or rhythmic suction on the lung at 8 to 12 mm. Hg alternating with nitrogen inhalation. The main point is that for the best results both active suck and blow are necessary. Suction must be active, because with mere passive expiration action currents are not set up in the nerves involved, whereas with active suction they are. Thus with rhythmic inflation and suction a powerful reflex mechanism allows temporary resuscitation to take place in the experimental animals with the use of only inert gas—that is, without oxygen. The circulation recovers regularly before spontaneous respiration begins. The addition of 10% CO_2 to the inert gas inhibits this resuscitation, as do bilateral vagus section before asphyxia is started and, to a less extent, denervation of the carotid sinus. The reflexes concerned apparently arise not only in the vagal endings in the lungs and cardio-aortic region but also in the carotid sinus area, and travel by the corresponding afferent nerves to the medullary centres—vasomotor, cardiac, and respiratory. As a result of these animal experiments it is suggested that, clinically, in advanced asphyxia when the respiration has ceased, oxygen alone or oxygen plus carbon dioxide should be administered by the suck-and-blow type of resuscitation, within safe limits of pressure.

MAN AND HIS ENVIRONMENT

Mr. A. M. Carr-Saunders[1] has recently reminded us that we find it more attractive to think of mastering our surroundings than of mastering ourselves. The pioneer efforts of Galton in the latter direction were weakened by his conventional class-consciousness and lack of appreciation of social problems; still truer was this of some of his disciples. Consequently professional biologists stood rather aloof; and indeed, until the rediscovery of Mendel's work laid bare the mechanism of inheritance, eugenics could hardly claim to be a science. The obstacles in the way of making a genetic analysis of man are immense, but it will be seen that the results obtained so far do not clash seriously with Galton's intuitive conclusions. We must remember that inheritance merely means that offspring get their genes from their parents, while environment includes for man not only physical factors, as for all animals, but also the provision of opportunities for learning. The object of social organization is not standardization but the creation of conditions under which genetically unique individuals (which we all are) can best fulfil the promise that is in them. Unfortunately there is reason to suspect that the genetic material in any civilized society deteriorates slowly but almost certainly, for harmful mutations are preserved which would perish under cruder conditions. True, they are compensated for, but that is not cure, and their persistence must be injurious to the common stock. There are always some people of subnormal mind and physique who cannot hold their own in the circle in which they were brought up and who, therefore, tend to sink. The damage is enhanced by the inverse relation between social class and fertility, even though this is now on the wane except in the lowest group of all. In the other strata the average of intelligence does not vary greatly. But the danger of unfavourable mutations occurring and being encouraged to persist is insidious, for there is a not inconsiderable element in the population which by reason of inferior hereditary endowment cannot take advantage of a good environment. Carr-Saunders, in his interesting review of the biological basis of human nature, brings to his support J. B. S. Haldane.

Mr. H. S. Souttar, Chairman of Council of the British Medical Association and chairman of the Central Medical War Committee, has been made chairman of a mission to report on the medical services for the armed Forces in India. Prof. R. M. F. Picken has been appointed acting Chairman of Council during Mr. Souttar's absence.

A Royal Medal of the Royal Society has been awarded to Dr. W. W. C. Topley, F.R.S., for his outstanding work on experimental epidemiology and immunology, and the Buchanan Medal to Sir Wilson Jameson for his distinguished administrative service to hygienic science and practice.

The next session of the General Medical Council will open on Tuesday, Nov. 24, at 10 a.m., when the President, Mr. H. L. Eason, will take the chair and deliver an address.

BY

Sir WILLIAM SAVAGE, M.D., B.Sc.

(*Concluded from p. 585*)

Epidemiological Features of Food Poisoning

The epidemiological features of food poisoning merit some attention. I have already mentioned the physical condition of the food. Seasonal prevalence is much higher in the summer, particularly so for Salmonella outbreaks and those of other living bacilli. The infectivity rate varies considerably, and, except in botulism, not all the people who have taken the food become poisoned. In an outbreak from a toxic staphylococcus less than half the people who have eaten a particular food may be attacked; with living Salmonella poisoning the proportion is usually much higher, but all consumers are not invariably affected. There is practically no case-to-case infectivity unless people are really dirty in their habits. The case mortality with living Salmonella is from 1 to 2%; with the toxin outbreaks it is practically *nil*; in botulism, however, it is 60 to 70%.

The nature of the food vehicle is important. In botulism it is something which has been maintained under anaerobic conditions and often kept under wrong conditions. Botulism can arise from home-canned foods because the heating has been inexact, but in modern practice it very rarely occurs with the commercially canned article. With Salmonella, the more food is manipulated the more it is apt to be a danger. Slightly manipulated food like ham does not cause so many cases, but when we come to much-manipulated foods like brawn, meat pies, or ice-cream, the liability is increased. Tables I have published show very clearly the association of food poisoning with human food handling.

In Salmonella poisoning the three cardinal symptoms—diarrhoea, vomiting, and abdominal pain—are almost invariably present. Others are rise of temperature, nausea, and cramps, but these vary. The clinical distinction between the different types is important. Botulism can be distinguished by its characteristic symptoms. The toxin type may be due to staphylococci or it may be due to toxins of other organisms. If it is the toxin type you can usually distinguish it at once. Most important is the very short incubation period, while usually the onset is acute. The symptoms may be severe, but they last only a short time and recovery is rapid. This follows from the fact that the sufferer is taking into the body with this food all the poison at once; none is manufactured in the body. Therefore it acts quickly and its onset is abrupt. Directly it has sufficiently irritated the stomach and intestine it begins to act. It does not last very long, and when the toxin is eliminated the patient gets better. On the other hand, with living Salmonella bacilli the position is different, since the bacilli multiply inside the body. The incubation period will be considerably longer than for the toxin type, the length in part depending upon the amount of preformed toxins introduced. The bacilli have to establish themselves in the duodenum or jejunum and to grow there and manufacture their toxins. There is a gradual dosing with toxins, and the malady lasts a good deal longer. If these considerations are kept in mind confusion between the different types is unlikely.

Investigating Cause of an Outbreak

Given an outbreak, what are the lines of action? I cannot go fully into the public health side, but we have to endeavour to find out certain things. No investigation is complete unless four things are ascertained. The first is the vehicle of spread; the second is the causal agent, such as toxin or Salmonella. But that does not end the matter. So many of the reports I read include those two points and then those who write them appear to think they have finished their job. There are two more things to know. One is the reservoir from which the organism passed to the vehicle; the other is the path by which the organism was conveyed to the vehicle from the reservoir. For example, with an outbreak of ice-cream poisoning due to *B. enteritidis*, the vehicle and organism are known. But we still have to ask how the Salmonella got into the ice-cream and from where. This may be from various sources, and when elicited we know the reservoir. As to the path, we may find that the ice-cream was put to cool in a chamber where there was evidence of rats; but that is rare. I have investigated hundreds of outbreaks, and in a great many I have not been able to prove every one of these four things, but in each instance I have sought for all of them.

The ascertainment of the vehicle is sometimes easy, sometimes difficult. It is necessary to inquire what was eaten by all the persons concerned. In a recent ice-cream outbreak of mine associated with the Sonne dysentery bacillus it was easy. There were two ice-cream vendors at a little country fair; one sold his wares inside and the other outside, and all the people who had the illness had bought their ice-cream from the man inside, while none of those who had bought it from the man outside were ill. Then I found that this inside man had a regular itinerary and that wherever he stopped to sell his ice-cream there were sporadic cases of ice-cream poisoning.

In making an investigation leading questions must be avoided. Do not jump to a conclusion and say, "Did you eat that?" All the people must be asked in turn what they ate, and this inquiry may point to one particular item. It is quite useful to have a typed list of all the foods available at the peccant meal and ask every person who took part (whether sufferer or not) to tick each article eaten. I have had occasions when cases have occurred after banquets or parties, and it was discovered that the remnants of the food went to somebody else. If there is illness among those to whom particular foods were afterwards distributed that may clinch the matter. These ancillary inquiries are often exceedingly valuable in defining the vehicle at fault.

As regards the reservoir, that is a public health question. A large number of animals suffer from Salmonella diseases. These include most animals and many birds, but sheep very rarely. Rats and mice commonly suffer from these diseases, while ducks are susceptible. There have been a number of outbreaks in which ducks' eggs were concerned. When a custard seems to be the source of the trouble it is well to find out whether it was made from ducks' eggs. One has nearly always to look for an *animal* reservoir. In rats waves of Salmonella infections may occur and the bacilli may persist for long periods in the survivors. I have examined numbers of rats in slaughterhouses and have found a certain proportion harbouring Salmonella bacilli.

In a large proportion of outbreaks the investigator seeking the reservoir concentrates upon looking for a human carrier—a vain quest, for in general we do not get food poisoning from human carriers. The Salmonella organisms are gastro-intestinal irritants; they do not invade the body at all. An examination of the blood in cases always fails to show Salmonella bacilli. In other words, the Salmonella organism in food-poisoning outbreaks acts as a local organism. It stays in the gastro-intestinal tract (unless the patient dies) until it is washed out—quite different from *paratyphosus* B, which does not cause food poisoning but which does invade the blood stream. The ordinary food-poisoning types are local and it is a waste of time to look for a chronic human carrier. The human carrier is only seen as a hangover from an outbreak a few weeks earlier, before the bacilli have had time to be eliminated.

When confronted with an outbreak how should one deal with it? The first thing is to try to ascertain how many were ill, the magnitude of the outbreak, and the kind of symptoms from which the victims were suffering. This should be done roughly and not in full detail at the onset. The next point is to discover whether the outbreak is associated with a living bacillus, is a toxin outbreak, or is a botulinus outbreak. The symptoms and the incubation period will probably tell you right away what you are likely to be up against.

The next step is to ascertain the vehicle by inquiry and, if it is still operating, to stop its use. Sometimes it is most difficult to discover the vehicle, but do not leave it all to the bacteriologist to find it, for this is really an epidemiological job. It is unfair to collect samples of all the foods eaten and expect the bacteriologist to find the infected food. That may be necessary, but, done indiscriminately, is a waste of time. Having ascertained what is the vehicle, try to collect some of it for examination. Here some ingenuity must be employed. What are wanted are scraps left over from the food eaten. I have been able to isolate Salmonella from a tin thrown in the dustbin with a little food at the bottom of it. Do not be satisfied with a statement that the food has all been eaten. That is often not the case, and with persistence scraps of it may be found.

It is then important to go at once to the place where the food was made. In many outbreaks the investigator takes a lot of time collecting particulars of the cases and on the following day goes down to the shop where the meat pies or whatever is implicated were sold and reports everything beautifully clean. The shopkeeper is not a fool, and having heard of the matter everything is cleaned up. When you have knowledge of an outbreak go to the place of preparation (if there is one) *at once,* and then you are likely to find everyday conditions, including possibly a lack of cleanliness, remains of rats and mice about, and the like. A detailed inquiry elicits all sorts of things, while investigation should be made as to the habits of the staff regarding cleanliness. You may want to collect from the shop some of the food for the bacteriologist. Particular attention should be given to the way the food is cooled. A number of outbreaks have been caused by preparations like brawn, which are infected after being put out to cool. The slow cooling, perhaps for over twelve hours, enables specific infection to be enormously multiplied. I have known cases in which brawn was cooled by being put out on cellar steps. An examination should be made for all voided material suggesting rat and mouse infection.

The materials to send to the bacteriologist at once are the suspected foods, specimens of the vomit or faeces, and, in the case of death, post-mortem material. When there is death it is generally pretty easy to prove the nature of the infection. In many toxin outbreaks the bacteriologist finds nothing. If the outbreak is due to a staphylococcus which produces toxin, staphylococci will be found in the food, and one may expect to get the toxin; but in cases due to Salmonella toxins, with no bacilli present, nothing definite will be found. The diagnosis has to be made on the clinical symptoms and other facts. It is of no use sampling the blood in the acute cases for living bacilli. After a week from the onset blood for agglutination tests is most valuable.

With regard to prevention one has to find the cause and stop the vehicle. While case-to-case infectivity is low, nobody who is recovering should handle food until the stools are free from bacilli. In some recorded outbreaks the bacilli have persisted in the stools for a number of weeks.

CHRONIC SOURCES OF VENEREAL INFECTION

POWER TO ENFORCE TREATMENT

The following notes on Defence Regulation 33B have been supplied for publication by the Ministry of Health :

A new Defence Regulation 33B has been made which extends the powers available under the present law for the treatment of venereal diseases and enables compulsion to be applied in certain carefully defined circumstances.

Hitherto the arrangements for the treatment of these diseases in this country have been based exclusively on voluntary attendance for treatment, in contrast with the compulsory basis adopted in most other countries. The voluntary system has met with a large measure of success, and before the war the rate of incidence was low and compared favourably with the record of other countries. The new Regulation leaves the voluntary basis unchanged, but provides for compulsion, where necessary, to bring under treatment the group of persons—small in numbers, but responsible for a comparatively large amount of harm—who are impervious to methods of education and persuasion and who refuse to attend voluntarily for treatment although known to be infected and to be spreading infection.

In outline the Regulation provides that persons named by two separate patients under treatment as the suspected source of their infection can be required, by notice served on them by the medical officer of health of the county or county borough in which they live, to attend for examination and if necessary treatment by a "special practitioner," and to continue treatment in accordance with his directions until they are certified as free from venereal disease in a communicable form. A special practitioner is defined as a registered medical practitioner employed as, or qualified to act as, a venereal diseases officer of a treatment centre; or a specialist in venereal diseases in His Majesty's Forces or the Dominions Forces; or any other practitioner designated for the purpose by the Minister of Health.

The Regulation imposes on "special practitioners," on receiving information from a patient under treatment for venereal disease as to the person from whom the patient suspects that the disease was contracted ("the contact"), the duty of sending particulars in a prescribed form to the medical officer of health of the county or county borough in which the contact is believed to live. These particulars must be sent in each case unless, having regard to the information before him, the practitioner is of opinion that there is no reasonable cause to believe that the disease was in fact contracted from the person suspected. All information obtained is of course to be treated as strictly confidential.

A special practitioner is also required to supply free of charge any necessary certificates, and to serve on the contact (if found on examination to be suffering from venereal disease) a notice requiring attendance for treatment in accordance with his directions. The Minister has given certain general directions to special practitioners, as well as prescribing certain forms, and has compiled notes for their guidance. Copies of all these may be obtained from the Secretary, Ministry of Health, Whitehall, London, S.W.1, or from the medical officer of health of any county or county borough.

A special practitioner in private practice is under no obligation to undertake the examination or treatment as a private patient of a contact on whom a notice has been served by a medical officer of health; but if he does accept the contact as a private patient he must discharge the duties laid down in the Regulation. Any practitioner not otherwise qualified as a special practitioner who wishes to be designated as a special practitioner for the purposes of the Regulation should apply in the first instance to the medical officer of health of the county or county borough in which he practises, giving particulars of his experience in the treatment of venereal diseases.

Correspondence

Child Health

SIR,—Capt. Eric Townsend's letter (Nov. 7, p. 558) is excellent, for it goes to the very root of the matter. Child welfare clinics will never be any better until they are managed by those who have had a thorough training in diseases of infancy and childhood, including infant feeding and management. Those attached to a public health department are seldom, if ever, possessed of such knowledge. It has recently been decreed by the G.M.C. that this subject shall be taught clinically without the very necessary background of a systematic course of lectures. This, in my opinion, is a grave mistake. I have been teaching this subject for many years, and my experience is that young practitioners who have only attended a clinic know very little about infants and children or their diseases. It is essential that students should be compelled to attend a systematic course of lectures on this important subject. Unfortunately, the powers that be seem to have disregarded this either owing to ignorance or error on their part.—I am, etc.,

Edinburgh. JAMES BURNET.

Service Cases of Venereal Disease on Demobilization

SIR,—Post-war reconstruction is being widely discussed at present, and it therefore seems opportune that plans should be considered for the problem of dealing with Service cases of venereal disease on demobilization. We must avoid a repetition of the situation at the end of the last war, when many incompletely treated cases of V.D. returned to civil life and too often sought no further treatment. Much of the tertiary syphilis encountered in the past decade appears to have resulted from early disease inadequately treated at that time. Further, the Services are constantly discovering unsuspected cases of congenital syphilis in men in their twenties, and many of these can be attributed to the same premature cessation of treatment in their fathers.

Even if on demobilization incompletely treated Service patients are given adequate details of the treatment they have received and are advised to continue their course at a civilian clinic, it is probable that only a small percentage will actually do so in that reactionary period. We shall require an "Army of Occupation" when an armistice comes, and with modern treatment it would not be incompatible with the efficiency of such an Army if V.D. cases were retained in the Services until the full standard treatment had been completed to the satisfaction of the authorities. We might thus prevent a considerably increased incidence of tertiary and congenital syphilis in the next generation and avoid an epidemic of early syphilis in the immediate post-war period. The problem might well be discussed now so that suitable arrangements can be prepared in advance.—We are, etc.,

DAVID ERSKINE.
Guy's Hospital, S.E.1. V. E. LLOYD.

Control of Venereal Diseases

SIR,—As a clinical (V.D.) medical officer may I be extended the courtesy of your *Journal* to express my thanks to Col. L. W. Harrison and Dr. P. W. Hamond for their well-timed letters (Oct. 31, p. 528) in regard to the correct use of sulphapyridine in the treatment of gonorrhoea. I need hardly say that I endorse their remarks to the full. The common practice of administering sulphapyridine in cases of definite or suspected urethritis without taking preliminary steps to establish a diagnosis is clinically unsound and may result in tragic sequelae. The ritual of prescribing such a drug in total disregard of methods which have proved universally effective in the vast majority of cases is far more serious a matter, and may have far-reaching and untold deleterious results. It is quite trying enough to have to deal with one's own cases of drug-resistance, but when they arrive "ready made" on the doorstep it is sufficient to test the patience of a Job!

May I add an appeal in regard to another clinical procedure which is equally frequent in my experience and causes no end of trouble—namely, that of applying any form of antiseptic to genital lesions which may or may not be manifestations of early syphilis until such time as that diagnosis has been definitely ruled out. Much valuable time in arriving at a diagnosis, and instituting treatment if necessary, will be saved if this simple regime of "masterly inactivity" is observed. Venereal diseases clinics are provided to deal with all suspects and/or sufferers from such diseases, and I would earnestly ask all practitioners to refer their cases direct without recourse to previous efforts relative to diagnosis or treatment. By adopting such a line of action I am confident that the health of the whole community, individually and collectively, would derive inestimable benefit.—I am, etc.,

Durham. W. GILLIES ANNAN.

Sulphonamides for Gonorrhoea

SIR,—A few years ago Col. L. W. Harrison stated in the *B.M.J.* that "it is better to wait until the attack [of gonorrhoea] has lasted 3 weeks before starting treatment with any of the remedies [i.e., sulphonamides]." Now he says that "sulphathiazole eradicates the disease in 2 days in 90% of cases." This too optimistic statement cannot be allowed to go unchallenged.

If the patient presents himself within 4 days after coitus—just as the inflammation is beginning to show itself in the mouth of the urethra—sulphathiazole would work the above wonder. But the same result has been obtained in the past by injecting 20% argyrol 3 times a day and sealing the urethra up by pressure for 15 minutes. The patient now, as before, asks for treatment when the discharge is fully established and thick pus is pouring out of the urethra. To expect sulphathiazole to cure this case in 4 days is to expect a miracle, and it never happens.

For successful treatment all patients (especially soldiers) should be put on the sick list for 2 weeks and ordered to irrigate with a bulbous-end glass syringe 3 times a day, using permanganate solution 1 in 4,000. I have found the big douche-can quite unnecessary and even harmful in acute cases. Sod. sulphathiazole 1 gramme every 4 hours (during day and night) should be given to the robust and every 6 hours to the others for 4 days.

The disappearance of gonococci from the urethral smear or from a centrifugalized specimen of urine after prostatic massage is not a proof that gonorrhoea has been eradicated. So long as pus cells and threads are present the case should be treated as infectious. There has been a great increase recently in the number of young women suffering from vaginitis of non-specific origin. Is it not possible that men who have got rid of their gonococci by taking sulphathiazole for 4 days have introduced other organisms into healthy vaginae and caused the above condition? To cure a woman of vaginitis is not a matter of days but weeks and months. No woman is ever cured by douching at home, inserting pessaries, and taking sulphathiazole or sulphapyridine by the mouth.—I am, etc.,

Withington, Manchester. M. R. SONI.

Vitamin C and Resistance to Infection

SIR,—In reference to your annotation (Oct. 31, p. 518), I think that it is important to emphasize the other side of the picture. The boys in this institution were crowded together into badly ventilated dormitories and exposed to a virulent haemolytic streptococcal infection. Yet many of them achieved a high degree of immunity without ever falling ill, smoothly and silently, in spite of an intake of only 10 to 15 mg. of vitamin C daily (Thomson and Glazebrook, *J. Hyg.*, Camb., 1941, **41**, 570).

There is, of course, a wide variation in the susceptibility to hypovitaminosis C among individuals, and conclusions drawn from experiments on individuals are not of much value. This variation in susceptibility extends to tissues too, so that scurvy may first show itself as a gingivitis or an anaemia; while both conditions are commonly absent in frank scurvy, in my experience. One reason for these varying clinical pictures, besides local tissue susceptibility, is that additional factors are usually required to precipitate illness in latent scurvy. The factor may be, for instance, a suboptimal intake of iron or of the anti-pernicious anaemia factor insufficient in itself to cause an anaemia. In the presence of vitamin C deficiency the interplay of factors produces a hypochromic or hyperchromic picture, curable in either case by vitamin C. Thus, scorbutic gingivitis may be regarded not so much as a manifestation of scurvy but as a gum reaction to toxins or local infection in the presence of vitamin C deficiency. The gums will heal when treatment is directed to whichever of these factors is predominant. As an example, 300 cases of gingivitis in adults whose intake of vitamin C was low were examined. All showed evidence of varying degrees of vitamin C deficiency, 27 refused to heal until local treatment was stopped and vitamin C given. The remainder healed quite well with local treatment only. It is probable that vitamin C would have accelerated healing in these cases, but the planning of the experiment did not allow of this.

It seems that vitamin C plays a relatively minor though essential part in resistance to generalized infections, just as it plays a minor though essential part in haematopoiesis or in the maintenance of healthy gum tissue. Many boys aged 16 can lead healthy lives on an intake not exceeding 15 mg. daily. Their existence is a precarious one, however, for once a serious breach is made in their defences the tissue reactions are inadequate and their attempts at repair clumsy and laborious.—I am, etc.,

Royal Infirmary, Edinburgh. A. J. GLAZEBROOK.

⁂ We apologize to Dr. Glazebrook for misspelling his name in our recent annotation.—ED., *B.M.J.*

Prevention of Small-pox

SIR,—Dr. C. Killick Millard criticizes the mass revaccination method of combating the recent small-pox epidemic in Glasgow. It would be interesting to know, as he says, the total amount of time lost through revaccination and compare that, not with the time lost through immunization against diphtheria, but with the total amount of time lost through small-pox, including, of course, an estimate of the time lost through deaths.

He states that such a drive as has been practised in Glasgow inevitably gives rise to "scare." I have no inside knowledge about the late epidemic, but I know something about the previous one when about 400,000 people were revaccinated. The "drive" was nearly a week behind the "scare" or, more correctly, "panic." After the epidemic had been smouldering for some time a rumour got about that there had been 50 new cases of small-pox over the week-end in my district. I believe that was the number for the whole of Glasgow. When I went to my consulting room on the Monday evening I found a crowd at the door and my waiting and consulting rooms packed. When I asked what was wrong, the answer was, "We want to be vaccinated." No one offered to pay. They all expected that the town would pay. When we rang up the M.O.H. he said he would let us know, but it was several days before he told us that we should be paid. In the meantime we had to note the names and addresses of those we vaccinated and the results. Thus every general practitioner became a public vaccinator in fact if not in name and freed the M.O.H. and his staff to attend to what Dr. Millard calls "really important matters." Personally, I think revaccination was the most important matter at this time.

The year after that epidemic there was another one with 500 cases. I was informed by the superintendent of the small-pox hospital that not one of these cases had been revaccinated. So that the 400,000 who were revaccinated had 100% immunity. Dr. Millard is not logical in stating that he has a profound belief in the utility of selected individual vaccination and yet objects to mass revaccination during an epidemic. To depend on following up contacts alone without revaccination seems like trying to empty a bucket with a sieve. For one contact that is known there are probably dozens that are not known. Here are some examples.

Coming home late one Saturday night I found three people waiting for me in the hall. The first, a man, said he had a rash on his arms. He had small-pox. The other two I revaccinated at once. That man had been to a football match and had travelled in several trams. How many contacts had he made during that day? A baby, 17 days old, I found suffering from small-pox. On inquiry I discovered that the grandmother, who had visited it every day, was not very well. I went and saw her and found she had just recovered from small-pox, but had been about all the time, going into shops, etc. I had heard of a woman who was going about with a shawl over her head and most of her face, and this was the woman. I wonder how many people got small-pox from her.—I am, etc.,

Birmingham ROBERT ANDERSON, M.D.

The Dysentery Carrier

SIR,—In England and Wales the annual notifications of dysentery have shown a marked upward tendency during the last seven years, and the figure for 1941 was considerably higher than in any year since the disease was made notifiable. The increase in recent years was apparent well before the war, and cannot, therefore, be ascribed to wartime conditions. It is probable that the increase is due in part to the fact that we are becoming more bacteriologically minded, but even so, a considerable number of dysentery cases are still not fully investigated and do not appear in the notification records.

Modern sanitation, pure water, and safe milk have largely abolished the menace of intestinal infectious diseases. How is it, then, that dysentery seems to be increasing? There can be only one answer. We know that the disease is kept alive by the presence of carriers and "missed" cases; and we know that if carriers observe scrupulous care, particularly in the hygiene of the toilet, they cease to be dangerous to others. Each case of dysentery probably means that somebody has been careless in personal hygiene, and an outbreak usually means that the person at fault is a food handler. The prevalence of dysentery may be taken as an index of the standard of personal hygiene in the community.

Two things are necessary—the provision of washing facilities and education of the public in the importance of their use. Legislation has now ensured the provision of washing facilities and soap and towels for food handlers, but only education can ensure their regular use. There is room for improvement in the standards of hygiene in the home, at the place of work, and in public places. Too often it is found that the conscientious citizen is penalized by having to pay the extra cost of a "wash and brush up."

It is not enough merely to teach the subject of hygiene in school classes. Good habits should be inculcated until they become second nature to the children. The public should not be permitted to retain the present universal belief that attacks of diarrhoea are the inevitable consequence of wartime food and conditions. Such complacency leads to an increase in the number of undiagnosed convalescent dysentery carriers. Publicity on intestinal infections and their relation to personal hygiene would not be easy, but it should be within the means of publicity experts to devise and propagate suitable material, even for this unattractive subject.—I am, etc.,

London, S.W.1. IAN TAYLOR.

Epidemic Hepatitis

SIR,—Earlier this year (April 11, p. 466) you published a short account by me of a series of cases of epidemic hepatitis that occurred in this district in September and October, 1941. The following report on the subsequent course of the disease may be of interest.

Onset of last case in the 1941 series, Oct. 22, 1941; onset of next case notified to M.O.H. in Jan., 1942. This first case in the present year was followed by a second case in the same family in February, and on April 10 a third member of the family developed icterus. There were two other cases in March and April, the dates of onset being March 17 (the child was a playmate of the family in which there were three cases) and April 18. These two children and the family of three all attended the same school, and two of the families were, as stated, close friends. All five children developed icterus after an illness with a coryzal onset.

At the other end of the town three cases occurred as follows: (1) onset of icterus March 15; (2) first symptoms April 1, icterus April 8; (3) first symptoms April 10, icterus April 15. All these patients lived near one another, attended the same school, and their illness began with abdominal symptoms. After this there was an interval of 4½ months before the next case was notified; in this the coryzal onset was on Aug. 27 and icterus appeared on Aug. 31. No further case has been notified up to the date of writing, Oct. 21.

It is unwise to draw conclusions from a small series of cases, but it would appear that the incubation period may well be one month—e.g., the family of three and their playmate developed icterus at intervals of one month. The disease is not notifiable, so that there may well have been other cases during the closing months of last year and during the summer of this year, or the infection may have been kept going in the district by subclinical cases, or the initial patient in any series may have contracted the infection outside the district. There are still many points for elucidation in this affection, and the collection and correlation of reports from as many sources as possible would be of service.—I am, etc.,

Mirfield, Yorks. C. GRANT NICOL.

Control of Malaria in Palestine

SIR,—In the leading article on the control of malaria in Palestine (Oct. 31, p. 517) it is stated: "Perhaps the most noticeable feature in respect to species is that *A. maculipennis*, which assumed such importance in Macedonia in the last war, does not occur." This is very far from being the case. *A. elutus*, the dangerous malaria vector in rural areas of Palestine, is one of the varieties, or races, of *A. maculipennis*. It is indeed the very variety that is responsible for most of the malaria in Macedonia. *A. maculipennis* var. *elutus* in Macedonia appears to have a more marked predilection for slightly saline breeding places than does its Palestinian prototype, but no other differences have, I think, been recorded.—I am, etc.,

Bicester. NORMAN WHITE.

⁂ As the passage referred to in Dr. Norman White's letter is evidently liable to give rise to some misconception a word of explanation is desirable. *A. elutus* Edw. (more correctly *A. sacharovi* Favr), though originally described as a species resembling but distinct from *A. maculipennis*, was for some time frequently treated by authorities as one of the five or six varieties of this species. It is now, however, generally considered and referred to as a species in its own right. That *A. elutus* was mentioned in the leading article among the three species playing an important part as carriers in rural areas in Palestine should have been an indication that it was so regarded both by the author of the report and by the reviewer. *A. maculipennis* in any of its varieties (if we except *elutus* as not being a variety but a distinct species) has never been recorded from Palestine, an interesting fact in distribution which is repeated further east where in Iraq *A. maculipennis* is not encountered going north until at or beyond Mosul, although incidentally *A. elutus* has been recorded from Basra some hundreds of miles to the south.—ED., *B.M.J.*

Tetanus

SIR,—I was extremely interested in the article on this subject by Dr. Leslie Cole (Nov. 7, p. 550). I agree in general with his able article, but I should like to add a few points which I developed in treating a case a few years ago.

The patient was a gardener aged 52 and he developed tetanus after pricking his finger while at work. I kept him under continual avertin anaesthesia for 6 days, giving a full surgical dose per rectum every 12 hours during this period. I kept his lungs dry with atropine and sustained him with a rectal drip of saline and glucose. I gave no antitoxin as I believe that if the spasms can be controlled the body will produce its own antitoxin in due course. In my case the patient recovered in some 10 days' time and is alive and well to-day. I had some difficulty with breathing, but found that nasal doses of CO_2 from time to time restored respiratory rhythm.

As this disease is common on the battlefield, more attention will have to be given to it than in the past.—I am, etc.,

Weybridge. JOHN H. HANNAN, M.D.

First-aid for Fractured Spine

SIR,—My thirty years' experience as an industrial surgeon has shown me that fracture of the spine is a far less uncommon injury in the heavy industries than is usually appreciated. In the absence of repeated *x*-ray examinations cases are overlooked until later disabilities arise. An essential link in the chain of cure is a specially trained industrial first-aid team. It is important that the idea should be removed from the first-aider's mind that paralysis is a sign of a fracture of the spine. His duty is to recognize the simple fracture, and by his handling of the case to avoid the complication of cord damage.

Having to deal with large numbers of first-aiders and to face on the operating table and in the hospital ward the failures of my teaching, I evolved a method of handling these cases that proved most satisfactory and which the first-aiders learned without difficulty. I am strongly of the opinion that fractures of the thoracic and lumbar spine must be transported face downwards with a firm pad—e.g., rolled-up blanket—immediately below the clavicle and immediately above the knees. The method of turning the patient on to his side, and the stretcher on to its edge to meet him, I found not only unsatisfactory but dangerous.

I shall be pleased to supply any of my colleagues who may be interested with details of my method of turning, lifting, and carrying cases of fracture of the cervical and of the lumbo-thoracic spine. I fear it would occupy more space in the *Journal* than in wartime the Editor can spare.—I am, etc.,

THOMAS E. A. STOWELL, F.R.C.S.,
Chairman, Advisory Medical Committee,
Industrial Welfare Society.

Westminster, S.W.1.

Shock Treatment in Psychiatry

SIR,—Your admirably balanced assessment of the new methods for the physical treatment of the psychoses (Oct. 3, p. 397) is welcome. It required to be more widely known that much can be done for the early schizophrenic with insulin and for the depressive with convulsion treatment, and that convulsion is not a promising treatment for schizophrenia. Furthermore, it has been made clear why, in the face of better knowledge, convulsion has been so extensively applied to schizophrenics to the neglect of insulin, and that the prospects offered by the latter are favourable enough to make an acute treatment centre a communally profitable enterprise.

For want of facilities most early schizophrenics—i.e., those sent to public mental hospitals—cannot be given insulin (there are a few exceptions), and only a few can avail themselves of the facilities offered by some private and registered institutions. I fail to see the logic of Dr. K. A. Graf's argument that it would be difficult to get in touch with the early cases, since most public mental hospitals run independent villas and clinics for this very purpose, only they simply have not the staff and the time to undertake the far more exacting insulin treatment.

I trust your statement that "for the early schizophrenic . . . this latter use [convulsion] instead of insulin is, except in the rarest cases, really disastrous" may not be misread as implying that, rather than give the early schizophrenic convulsion in default of insulin, convulsion should be withheld from him altogether. No one, however much convinced of the merits of insulin, would wish to see that happen, and, until your scheme has been put into operation, we shall have to cut our coat according to our cloth. I write as one responsible for the introduction of insulin shock treatment into this country, and have always regretted the tendency to regard convulsion as a cure-all (Dec. 31, 1938, p. 1390). I have seen, however, what can be done with convulsion even in schizophrenics, provided it is combined with sustained psychotherapeutic encouragement as taught by Meduna. Pioneers see a great deal of their patients between treatments, but once the method has become popular patients are more and more left to themselves between treatments. The latter does not so much apply to insulin, where the physician willy-nilly has to be with his patients 5 hours each day during several months, but it certainly applies to convulsion; as far as this goes, the universal introduction of foolproof electrical apparatus is to be regretted, and only recently FitzGerald and Saul (June 13, p. 736) said they saw it coming when the house-surgeon would be left "to press the button." Also, your observation, all too true, that results obtained by haphazard playing around with insulin and convulsion cannot be compared with those obtained by system and planning applies even more to convulsion, where judicious spacing of the fits may make a great deal of difference, and where results are more liable to be frittered away by want of persistence and perseverance.

I trust that these remarks will not be misunderstood: the aim is to provide insulin for the early schizophrenic throughout the country, but until then we shall have to get the best out of convulsion.—I am, etc.,

Falmouth. H. PULLAR-STRECKER.

Dressing for Thiersch Grafts

SIR,—The late Sir Henry M. Gray, who gave so many good things to the profession, used to leave his skin grafts bare whenever possible. This allows one to snip any blebs that form. The atmosphere under the cradle should be kept moist. One can generally tell if a take is probable before the patient leaves the table. The old "Worth's patent buff strop"—now, I fear, unobtainable—gives such a splendid edge to a razor that anyone with a little practice can cut large sheets of graft. These, when left alone by Gray's method, give the best results I have seen; but I can recall cases in which pressure by sponge rubber might have prevented a loss of the graft. It is often found that the basal cells have taken in this type of case.—I am, etc.,

London, W.1. G. H. COLT.

Aortic Regurgitation and Mitral Stenosis

SIR,—In his paper (Oct. 24, p. 473) on some aspects of carditis Dr. T. F. Cotton states that out of 194 cases of valvular disease 38 had aortic regurgitation and mitral stenosis. Surely some of these must have been cases of aortic regurgitation with Flint's murmur and no mitral stenosis. In 1862 Austin Flint first pointed out that when a presystolic murmur was heard in aortic regurgitation, only a small proportion of cases had mitral stenosis. In 1901 Thayer, at the Johns Hopkins Hospital, found that "in 45 post-mortems of cases of aortic regurgitation with a presystolic murmur only 12 had any mitral stenosis, and in these the pulse was noted as not large, and in most of them there was a loud snapping first sound at the apex."

Mitral stenosis would be incompatible with life if there was much aortic regurgitation; blood would never get through a stenosed mitral orifice against the pressure in the left ventricle; and, where the pulse is large and collapsing, no mitral stenosis is found post mortem. The probable explanation is that the regurgitant stream from the aorta strikes against the anterior flap of the mitral valve and causes vibrations in it, which produce the presystolic murmur and thrill.—I am, etc.,

Hove. WALTER BROADBENT, M.D., F.R.C.P.

Tonsillectomy: Guillotine or Dissection?

SIR,—Mr. T. B. Jobson, in his article on tonsillectomy by guillotine and dissection, seems anxious to revive a controversy which by now must surely be on its last legs. What a pity to delay the guillotine on its journey to the scrap-metal campaign. What good can come of its reintroduction now? Mr. Jobson has a lot to say against it, but the implication of his article is that he uses it extensively himself, and would probably have other people do the same. He gives a list of reasons why satisfactory results are not obtained from its use, but the concluding note, together with his golfing analogy, implies that all its disadvantages can be successfully overcome by the expert after some hundreds or thousands of practice shots.

There is a most impressive silence in the article on the treatment of adenoids in the guillotine method. It is now universally recognized that complete removal of adenoids in children is in every way as important as the complete removal of tonsils. Who, having watched the guillotine method of tonsillectomy, with its hurried manipulations terminating in a rising tide of blood, could believe that the stage is now ideally set for the removal of the adenoids? The lightly anaesthetized patient is turned over, and against a tightening barrier of resistant palatine muscle the curette is forced into the nasopharynx and blindly swept over its posterior wall. The tonsils may have gone completely, but there is many a pad of adenoid tissue which escapes that cramped unseeing sweep and lives to infect on another day.

At the Hospital for Sick Children, Great Ormond Street, where tonsil dissection has been employed exclusively since Mr. Waugh's campaign in 1909, the registrars are carefully instructed to take as much time as necessary to perform a completely satisfactory operation when removing the adenoids. This involves a digital examination of the posterior nasopharynx in the *fully anaesthetized* patient, followed by a careful curetting of the posterior wall with a sharp curette, first in the midline and then a sweep on either side around the Eustachian cushions, and then another careful digital examination. Complete haemostasis is secured before the anaesthetic is stopped. All this can only be done if the soft palate is fully relaxed—that is to say, if the patient is fully anaesthetized and without any pharyngeal reflexes.

The adenoid tissue left behind in the guillotine method may be high up on the posterior nasopharyngeal wall or distributed on either side and overhanging the Eustachian openings. Often it hypertrophies, and, becoming infected, causes chronic sinusitis, post-nasal catarrh, Eustachian blockage, catarrhal deafness, and is the focus of infection of the neighbouring lymphatic tissue. Removal of such offending tissue was a frequent operation at Great Ormond Street, where the patient reported after a successful tonsillectomy elsewhere but still suffered the old symptoms on account of retained infected adenoid tissue. Such cases can be seen again and again at E.N.T. hospitals. The guillotine operation as practised by the majority of its exponents does not give the necessary time, the sight, or the necessary palatine relaxation for dealing with the adenoids as an important and separate problem. The adenoids become a concluding gesture in a welter of blood and confusion.

No doubt in the hands of men like Sluder results of tonsil guillotining rise to 99.6% success, but what of the unfortunate cases dealt with by the professor in his early days? Mr. Jobson points out that the guillotine takes immense experience to handle really successfully and to produce results comparable with dissection. It would seem, therefore, that whereas great numbers of patients must have unsatisfactory operations at the hands of student "guillotineers," it would not be so in dissection, where the student has plenty of time to note and correct his errors and have his professor's criticism in time for it to be of use to the patient.

Finally, it is interesting to note that Sir StClair Thomson quotes tonsil dissection as being one of the oldest operations in the world, as Celsus (53 B.C.) wrote that "tonsils that are indurated should be disengaged all round by the finger and then pulled out." Few operative techniques can have such a worthy recommendation. It would be interesting to know whether there still exists a Celsus gag and tonsil-holding forceps listed among the instrumental monuments to be found in any current catalogue of ear, nose and throat instruments.—I am, etc.,

St. Ives, Cornwall. E. C. ATKINSON.

Working for a Salary

SIR,—The relative value of work done by salaried officers and by non-salaried medical workers is being increasingly discussed at the present time, generally with little regard to any factor other than the prejudices of individual writers. My own views may be properly subject to the same criticism, but I venture to point out two aspects of the matter which are commonly overlooked, and which were, I think, misrepresented by implication in Dr. Una Westell's letter (Nov. 7, p. 561).

Where a doctor is not in receipt of a fixed salary there is a very strong inducement (even if it is entirely unconscious) to consider the financial return of any course of professional action: the economic factor must essentially be pronounced. The worker for a fixed salary, on the other hand, is entirely free from considerations of financial competition, but so far from lacking stimulus in his work he has that much more energy liberated for the performance of his duties, and is stimulated by other forms of the competitive urge to vie with his colleagues in efficiency and to achieve minor fame as a successful exponent of his particular branch of medical work.

The most complete answer to any claims that a fixed salary leads to an unprogressive spirit is surely afforded by the fact that almost all prominent research workers are salaried officers of universities, yet they, more than any other branch of the medical profession, contribute to real scientific progress.—I am, etc.,

Weston-super-Mare CYRIL G. EASTWOOD,
Medical Officer of Health

Medical Officers of Health: A Recent Circular

SIR,—I should be very interested to hear the views of your readers, especially those who, like myself, hold positions under local authorities and whose interests are, therefore, primarily affected, on the meanings and implications of a circular letter which I, in common with my colleagues, have received from my chief.

The circular states that the council have, as a wartime measure, decided that the normal hours of work for the professional, administrative, and clerical staffs shall be fixed at a minimum of 39 hours a week (exclusive of the midday break). It further states that the council have also decided that any *authorized* overtime above the 39 hours shall be paid for as set out in the South Metropolitan District Council's recommendations, which are as follows: (1) to restrict the annual leave of all officers to two weeks; (2) to approve such increase as may be necessary in the working hours of officers, subject to the payment of overtime therefor.

These recommendations are subject to the following conditions:

1. Annual leave may be taken in one period of two weeks or in broken periods as the local authority may determine.
2. For the purpose of assessing overtime payable the "normal" working hours shall be assumed to be 39 a week (exclusive of the midday break), and the difference between such working hours and the wartime working hours shall be paid for at plain time rates of salary (exclusive of war bonus).
3. Hours worked over 46 and up to 52 per week (exclusive of meal-time breaks) shall be paid for at one and a quarter plain time rates of salary, and one and a half plain time rates of salary for hours over 52 (exclusive of war bonus).
4. Officers (male and female) with a basic salary exceeding £500 per annum shall not be eligible for the payment provided in (2) and (3) above, provided that an officer whose salary (excluding bonus) exceeds £500 per annum shall not receive less than any officer who is entitled to the payment provided in (2) above.

After enumerating 5 further conditions the circular proceeds:

10. No officer shall be adversely affected by reason of the application of these recommendations.
11. Any question arising between a local authority and its staff regarding the interpretation of these recommendations or any anomalies arising as a result of the operation thereof shall be determined in the first place by local negotiations or, failing agreement, by the District Council for the area, or, failing agreement, by the National Council.

The above, Sir, are what seem to me to be the essential parts of this circular. Many points spring to my mind in regard to the provisos contained therein. Here are a few:

1. The circular obviously applies to medical staffs (among others) working under local authorities. Most of these medical officers have

definite agreements with their local authorities, but, so far as I am aware, they have not been consulted on whether they would agree to the provisos contained in the circular, one of which, for instance, alters the conditions of service in regard to annual leave which in most agreements is fixed at four weeks for every eleven months' service.

2. Many of the medical personnel of public health departments have consistently for years worked much more than the 52 hours a week mentioned in the circular. Of these, some, such as resident medical officers in municipal hospitals, whose rate of remuneration is, say, £300 per annum with emoluments valued at £140 per annum, will qualify for the payment of overtime at what would appear at first sight to be a very handsome figure. Other, and more senior, officers, who by reason of their greater responsibilities or longer service receive a salary of £500 or over, are particularly excluded from participation in the proposed award for working overtime, but are nevertheless included in the provision which curtails their annual leave by 50%. Why senior officers doing more responsible work should suffer from this discriminatory treatment is not clear, unless the reason lies in the large sums of overtime pay which they might earn. To take my own case, for instance, I am in charge of an important subdepartment, and, apart from my four-weeks annual leave, am on call and therefore on duty for the whole 24 hours every day of the week, Sundays included. Clause 4 of the conditions set out above, however, debars me from any participation in overtime benefits, but permits my assistants to benefit as their salaries are below the figure of £500 per annum. It seems a curious state of affairs.

Could anyone enlighten me as to the identity and powers of the South Metropolitan District Council and the National Council, of whose existence I have been up to now completely ignorant? None of my colleagues to whom I have spoken appears to know any more than I do. Have the members of the National Council, whoever they may be, the right to make such recommendations as the above in regard to the conditions of service of medical practitioners without affording such practitioners the opportunity to discuss, agree, or disagree with any or the whole of such recommendations?

The views and comments of your readers will be much appreciated, and for obvious reasons I sign myself,

A.M.O.H.

Rehabilitation Centres

SIR,—I am sure Mr. G. R. Girdlestone's letter and the memorandum from the British Orthopaedic Association on the question of rehabilitation centres (Oct. 31, p. 526) will be read with interest.

The letter assumes that rehabilitation is a water-tight method of therapy which concerns wounds and accidents, and extension of this service under the same administrative and surgical control is advised. Rehabilitation is, in truth, a method of treatment which concerns disease as importantly as injury. For instance, it is of the greatest interest and importance to the neurologist and to the general physician, more especially to those interested in the chronic rheumatic diseases. It would be a retrograde step if rehabilitation centres were placed under surgical control, for the viewpoint would be narrowed, and the best use would not be made of these centres. Recognition that rehabilitation is a matter which concerns the physician as much as, or more than, the surgeon would be a forward step with great possibilities both now and in time to come.—I am, etc.,

London, W.1. ERNEST FLETCHER.

Hyperostosis Frontalis Interna

SIR,—I read with great interest Dr. C. T. Andrews's article (Aug. 15, p. 185). It is an interesting subject, especially if one considers that practically women only are affected by it and men only by leontiasis ossea. It seems to me that its occurrence must be connected with the endocrines and conditioned by them, as it appears that the same glandular fault will lead to the one in men and at certain periods (pregnancy, menopause) to the other in women; or is hyperostosis frontalis interna in women merely an arrested form of leontiasis ossea?

The case observed by me between 1935 and 1941 was in a woman aged 47, who in 1918 after her second pregnancy developed severe right frontal headache, which never left her. Four months after the confinement she had her first epileptic fit (grand mal). Since then she has had 3 to 4 fits yearly, most of them at night with incontinence of bladder, etc., and since 1934 these fits could be controlled by phenobarbitone, 1 or 2 gr., but never the headache. There is no epilepsy in her family nor any other familial disease. Her periods were regular and normal until 1940, when she was operated on for carcinoma of the left ovary. In 1935 she underwent cholecystectomy for chronic cholecystitis without gall-stones, and appendicectomy.

When first seen in June, 1935, clinically nothing abnormal was found, but the liver was felt and there was slight venous congestion over the right forehead. B.P. 120/65. Urine: albumin, sugar, urobilinogen, and porphyrin negative; sp. gr. 1013. There was frequency by day and night. Blood count: Hb 88%; R.B.C., 2,640,000; W.B.C., 7,600—eosinophils 2%, monocytes 7%, lymphocytes 32%, polymorphs 59%; poikilocytosis; microcytes and megalocytes were found but no megaloblasts or normoblasts. Wassermann reaction negative. Radiograph: hyperostosis of both frontal bones; pineal gland calcified; fundi normal; small bilateral central scotoma. C.S.F. and ventriculogram normal. Electro-encephalogram: small right frontal delta focus involving nearly the whole of the upper and frontal region.

There was prompt reaction to liver treatment, but no remission of the pernicious anaemia has been observed. Mental condition: not dependent on her general condition; easily depressed, easily paranoic, at times very dull, almost demented, only at rare intervals fit for her own home duties, always fatigued, and sleeps on an average 16 hours. Besides those epileptic fits, narcoleptic fits come on at irregular times after due warning.

This case of hyperostosis frontalis interna is of special interest as it is complicated by pernicious anaemia. Or is the same glandular or hypothalamic disorder responsible for both? In this connexion one is certainly reminded of those still rarer diseases Cooley's and Jackson's anaemia, both of which show skull changes in radiographs. Dr. Andrews is to be congratulated on his successful treatment with benzedrine. But, more important still, as he shows, the condition must be recognized and appreciated in the differential diagnosis of headache associated with general indefinite symptoms.—I am, etc.,

LEO RAU, M.D., M.R.C.P.
Lieut., R.A.M.C.

A Supply of Trained Male Nurses

SIR,—My committee—an association run by naval medical officers to help in assisting sick-berth staff to find suitable employment on being discharged to pension—desires to draw attention to a source of supply of well-trained male nurses whose position appears to have been overlooked in the framing of the reports of the Athlone and Horder Committees.

Very shortly, it may be stated that naval sick-berth ratings are trained at the expense of the Admiralty, and efficiently carry out the sick nursing at Royal Naval hospitals, R.N. depots, and on H.M. ships. Their qualifications and Service examinations for promotion in no way fall short of the requirements for the certificate of the State-registered nurse. After at least twenty years' service they retire on pension, and those who wish to make use of their training find themselves unrecognized as possessing any nursing qualifications. A letter to this effect has been sent to the Minister of Health. Many medical men at present serving as temporary naval medical officers must have had experience and felt the advantages of having such reliable, capable, and experienced sick-berth ratings to assist them in the treatment of the sick and wounded.

My committee thinks that more consideration and recognition should be given to men who have served their country for at least twenty years at home and abroad and have been efficiently trained by giving them a definite status in any nursing Act that may come into force.—I am, etc.,

J. FALCONER HALL,
Surg. Rear-Admiral (ret.).
Hon. Secretary, Central Council, Royal Naval
London, N.W.6. Sick Berth Staff Associations.

G. L. Maltby and M. Rosenbaum (*Proc. Soc. exp. Biol.*, N.Y., 1942, **50**, 10) have made an electro-encephalographic study of 17 patients in whom a diagnosis of eclampsia was made because of convulsive seizures associated with the latter part of the puerperium, the patients being studied from one week to five years after their admission to hospital. The electro-encephalograms of 77% of these patients showed a cerebral dysrhythmia, and in 58% there was a family history of convulsive disorders. Maltby and Rosenbaum suggest that in patients with eclampsia there may be a primary cerebral dysrhythmia, and that the associated toxaemia may act as a trigger mechanism making manifest the convulsive tendency.

Obituary

SIR NORMAN WALKER, M.D., F.R.C.P.Ed.

We announced last week the death of Sir Norman Walker, formerly president of the General Medical Council, which took place on Nov. 7 at his home in Midlothian.

Norman Walker was born at Dysart in Fife in 1862. His father, the Rev. Dr. Norman Walker, was a well-known figure in the Free Church of Scotland for many years. The son was educated at the Edinburgh Academy and afterwards went on to the University. He graduated M.B., C.M. in 1884, and took the M.D. four years later. His first post was that of resident physician at Edinburgh Royal Infirmary in 1885. During the next five years he engaged in practice in England, though near the border, in Cumberland, and there he remained until 1890, in which year he was president of the Carlisle Medical Society. It was in Cumberland that he met his wife, Annie Trimble, whom he married in 1887, and by whom he had three sons and one daughter. One of the sons, Dr. E. R. C. Walker of Aberdeen—and now a prisoner of war—is well known in the Scottish and central affairs of the B.M.A.

[W. and E. Drummond Young, Edinburgh.

Returning to Edinburgh, Norman Walker built up a reputation as a dermatologist. He had already spent a great deal of time on the Continent, especially at Vienna and Prague, where his mind received its bent towards dermatology, in which he was to specialize for the remainder of his medical career. His appointment as assistant physician in dermatology at the Edinburgh Royal Infirmary began an unbroken connexion with that institution extending over half a century, during which he became physician to the skin department and in later years consulting physician. He was also lecturer at the University. During his visits to the Continent he had become a disciple of P. G. Unna of Hamburg, whose work, *The Histopathology of Diseases of the Skin*, he translated from the German in 1896. He accomplished his task with notable skill and a general avoidance of foreign idiom, although to translate some of the terms into English was almost an impossibility. He had, fortunately, the help of Unna himself, with whom he had been on intimate terms for some years, and Unna more than once acknowledged his good fortune in having so competent an English translator who had become familiar with his work during many visits to his clinic. It was not Walker's first essay in what may be called heavy translation. He had already translated from the Norwegian the work on *Leprosy in its Clinical and Pathological Aspects* by Hansen and Looft. In 1899 he published the first edition of his own *Introduction to Dermatology*. This was a work of 250 pages, a reproduction of lectures which he had been giving to his students in Edinburgh, but it found an appreciative public and ran into many editions, the tenth being published forty years after the first.

As time went on Norman Walker became more closely identified with the University and with academic affairs in Scotland. He had a natural aptitude for university administration. He became a member of the Court and a curator of patronage. He was also inspector of anatomy for Scotland. Of the Royal College of Physicians of Edinburgh, of which he became a Fellow in 1892, he was for many years treasurer and was elected President in 1929. He was a Corresponding Member of the American, French, and Danish Dermatological Societies, an Honorary Fellow of the American Medical Association, and an honorary member of the Association of Military Surgeons of the United States. In 1906 he was president of the Fife Medical Association. He also took a conspicuous part in the organization of medical services in Scotland. During the war of 1914-18 he was chairman and convener of the Scottish Medical Services Emergency Committee, and later chairman of the Consultative Council for Medical and Allied Services, Scottish Board of Health. Another organization in which he was interested was the Highlands and Islands Medical Service Board, established by Act of Parliament and constituted in 1913. The Board did its work very thoroughly; there was no part of the Highlands and Islands, however remote, which was not visited by more than one member, and Norman Walker was as assiduous as any. In the B.M.A. he was at one time active, and always interested and friendly, though his official position in the G.M.C. later on entailed a withdrawal from participation in Association affairs. He was chairman of the Science Committee of the Association in 1906.

The General Medical Council

Sir Norman Walker was elected a member of the General Medical Council as the direct representative for Scotland in 1907 and so remained for more than thirty years. Here he found work after his own heart. For many years before his election to the presidency in 1931 he was Chairman of Business, which means aide-de-camp to the president and whip of the Council. For about a quarter of a century he was a member of the Executive Committee, the Penal Cases Committee, the Examination Committee, the Business Committee, and the Pharmacopoeia Committee. He was also a most useful member of special committees dealing with such subjects as students' registration, the prevention of unqualified practice, and the National Health Insurance Act. On his retirement from the chair of the Council in 1939 his successor, Mr. Eason, said that there was no problem which came before them which he could not simplify by reason of his familiarity with precedent and tradition.

One of his most noteworthy achievements for the G.M.C. was his two visits to all the medical colleges and several of the numerous medical schools of India. His reports on his return and his great familiarity with the position of medical education in India enabled the Council to deal effectively with the delicate situation which arose in connexion with Indian universities and their medical degrees. It had come to the notice of the Council that there was a certain laxity in the conduct of examinations in India, and it was thought that the regulations which students in this country were required to follow were not being observed out there. Sir Norman Walker's first visit to India took place in 1922. He was asked to undertake this task by Mr. Edwin Montagu, then Secretary of State. In spite of great difficulties and some bitter feeling which he encountered, he had the satisfaction, in conference with the Indian Universities authorities, of having his recommendations accepted. His tact and judgment and his sincere desire to promote sound professional education in India were acknowledged, and a more satisfactory measure of agreement was brought about, especially as regards training in obstetrics, than had previously existed. Without his assistance and knowledge the Council might have taken a false step in a difficult situation. He enabled the Council to shape its policies to the ultimate benefit of medical education in India.

In 1931, when Sir Donald MacAlister closed his long presidency, Sir Norman Walker was his obvious successor. For many years he and Sir Donald had been in closest association and friendship. Lady MacAlister in her biography of her husband mentions Sir Norman as "tirelessly kind and helpful." It is a remarkable fact that the G.M.C. for almost half its history should have had these two Scotsmen at its head. During his eight years of office in the chair Sir Norman proved an able, businesslike president, though he had not the brilliant qualities of his predecessor. But he was invariably courteous, quietly dignified, and a mine of knowledge on the history and procedure of the Council.

He received the honour of knighthood in 1923, his name appearing in the India Office list in recognition of the success of his efforts in his visit to the Indian Universities the previous year. Among other distinctions which came to him were the honorary degrees of LL.D. of St. Andrews, Edinburgh, and Bristol, and M.D. of Dublin.

R. E. MOYES, M.D.

T. A. H. sends the following tribute supplementing the memoir published last week.

The public and the medical profession of the North of England are permanently impoverished by the sudden death of Dr. Robert Esmond Moyes. Born at Largs in 1884, where his father was a well-known and respected practitioner, Moyes took his M.B., Ch.B. at Edinburgh University in 1905 and the M.D. in 1910. Soon after qualification he went into general practice in Broomhill and remained there and in the Warkworth district during his professional life, except for two years during the last war, when he served as a captain in the R.A.M.C. in Mesopotamia and Palestine. After the war Moyes took a great interest in the British Medical Association, and was president of the North of England Branch in 1939. Up to the time of his death he was a member of the Medical Advisory Committee of the Ministry of Health. He was always very interested in the Northern Counties Medical Society and was president during the 1923-4 session. He was chairman of the Northumberland Insurance Committee, and during the present war chairman also of the Northumberland Medical Recruiting Board under the National Services (Armed Forces) Act, 1939. Whatever work Moyes undertook he did to the best of his ability, and there is no doubt that his untimely death was largely due to overwork and that he was as much a war casualty as if he had been killed in action. In addition to being a man of outstanding professional ability, who would have distinguished himself in any branch of the profession, Moyes was a man of great human understanding. Few men of his generation can have so nearly attained the standard of the perfect doctor: his patients not only came to him with their ailments but sought advice, which they knew would be invaluable, whenever they were in a difficult situation. He gave his services to all classes of the community without any thought of reward or of his personal inconvenience. The memory of his unselfish devotion to duty, and of his warm human understanding, will remain during life with a very wide circle of patients and colleagues.

J. M. writes:

Early in his professional life Moyes joined the B.M.A. and for many years he has taken a prominent place in all its work. He has with much acceptance filled the various offices in the North Northumberland Division, and was specially successful, during the period when he was secretary, in greatly increasing the membership of the Association and in promoting enthusiasm in its work. He was a member of the Northumberland Panel Committee for many years, and at the time of his death vice-chairman. A number of years ago he was appointed chairman of the Northumberland Insurance Committee and conducted its business with dignity, and at all times promoted confidence between the profession and the laity. Moyes had a logical mind and was quick to assess the points of a question before arriving at his decision, and so clear was his reasoning that he seldom failed to carry with him those with whom he was deliberating. He was an ardent student and kept himself well abreast of the times, with the result that he was the trusted adviser of a large clientele in all walks of life. In his relations with his fellows he fulfilled the precept of the Good Neighbour: he was always ready to lend a helping hand to a colleague in time of need. Our sympathy goes out to his widow and daughter in this time of sore bereavement.

E. L. GOWLLAND, D.S.O., M.B.

We regret to announce the death of Lieut.-Col. Edward Lake Gowlland, D.S.O., for many years commandant of the Star and Garter Home for Disabled Sailors and Soldiers at Richmond and Sandgate. He died on Nov. 1, at the age of 65, in the home in which he took so much pride. He was the son of Richard S. Gowlland, chief secretary to H.M. Office of Works, and was educated at Christ's Hospital, then in the City of London, and went on for his medical training to St. Mary's. He graduated M.B.Lond. in 1901, and after holding the post of resident medical officer at Haileybury College he went into general practice at Faversham in Kent, remaining there until 1914. For many years he took a close interest in military affairs; he was a member of the Territorial Association for Kent, and from 1906 until 1915 he held a combatant commission as Major, R.G.A.(T.), commanding the Kent Heavy Battery and Ammunition Column. In 1915 he was gazetted to a temporary commission in the R.A.M.C.(T.), carried out distinguished service in the last war, and was mentioned twice in dispatches, receiving the D.S.O. in 1917. Later he was promoted lieut.-colonel commanding the County of London Field Ambulance. From 1921 to 1923 he was superintendent of the Ministry of Pensions Hospital at Orpington, and afterwards he became commandant of the splendid institution on Richmond Hill established by business men after the war as a means of alleviating those whom the war had disabled. Gowlland's professional interest was in the cases of paralysis and nerve affection resulting from war injury, and in 1934 he contributed an article to this *Journal* on the treatment of paraplegia following injuries of the spine and of disseminated sclerosis. Since 1938 he had added to his responsibilities that of emergency officer for Richmond.

Gowlland was president of the Harveian Society of London in 1933, and in 1936-7 he was chairman of the Richmond Division of the British Medical Association, which he originally joined in 1902. Among his colleagues in his local division he was much esteemed both for his organizing abilities and for his helpful and kindly manner.

Dr. Joseph Squier Hinnell died at Bury St. Edmunds on Sept. 30 in his 81st year, and in him the B.M.A. loses a loyal and active supporter and his patients and colleagues a trusted friend. Hinnell was by reason of his modesty and complete sincerity of purpose a most lovable man, who gave his 48 years of service as a general practitioner with whole-hearted unselfishness and was rewarded by the affection of all who knew him. Educated at the King Edward VI School at Bury St. Edmunds, at Pembroke College, Cambridge, and at St Thomas's Hospital, he was a man of exceptional clinical ability. for as surgeon to the West Suffolk Hospital for 47 years he not only took his share of general surgery but built up a considerable ophthalmic department: he developed also an extensive private ophthalmic practice in addition to his work as a general practitioner. His family, his public work, his practice, and the hospital—these were the interests of Hinnell's life and he sought no others nor asked for any other recreation. The loss of his two eldest boys, both of whom were medical students, left him unembittered, and he was consoled in his later years by a happy partnership with his son-in-law. Hinnell was nothing if not an individualist, and he refused at the outset to have any truck with the N.H.I. Without ill feeling but with great firmness he stoutly refused to go on the panel at any time. Those of us who knew him best are glad for his sake that he is not called upon to take a share in planning the medical service of the future with the prospect of an increasing measure of State control. It was to Hinnell and one or two others that West Suffolk owes its Armistice Day dinner, which, starting in 1919, was for twenty years the most popular annual medical event and was supported by many of our colleagues from further afield. A full and happy life of great simplicity and generous service. We miss him from our circle but do not grudge him his rest.—B. E. A. B.

We regret to note the death on Aug. 16 at Shanghai of Dr. H. Couper Patrick. He was the second son of the late William Patrick, M.D., a well-known practitioner in the East End of Glasgow, and was educated in Glasgow High School and Glasgow University, where he graduated M.B., C.M. in 1895. He spent a year as house-physician and house-surgeon in the Glasgow Royal Infirmary and a winter session in Vienna, and shortly afterwards went to India to do plague and famine work in Poona. Thence he migrated to Australia, and after a few years' practice there found an opening in Shanghai, where the rest of his professional life was spent. He was resident medical superintendent of Shanghai General Hospital and surgeon to the Lester Chinese Hospital. His wife was with him at the time of his death, and it is not known whether she has succeeded in obtaining repatriation to Australia, which both she and her husband had been trying to effect in the early spring of this year. Their only daughter fortunately is safe in Melbourne. Dr. Patrick took an active part in all Scottish societies and was at one time also president of the Shanghai Medical Society. He had been a member of the B.M.A. since 1903.

Dr. William Robertson of Huddersfield died on Oct. 16 in the Royal Infirmary, where he had been taken after being knocked over by a cyclist. Dr. Robertson was born in 1878 and graduated M.B., Ch.B. at the University of Glasgow in 1902. He had been in practice at Huddersfield for some 30 years and won the Military Cross in the last war while serving with the R.A.M.C. In the present war he was medical officer of a West Riding battalion of the Home Guard. He joined the B.M.A. in 1907 and was a member of the Huddersfield Medical Society.

The New York Correspondent of the *Times* reports the death in Philadelphia at the age of 73 of Dr. Edmund Louis Gros, for many years head of the American Hospital at Neuilly, France, and in 1916 one of the chief organizers of the Lafayette Escadrille. Dr. Gros, who was a Commander of the Legion of Honour, left France when the Germans invaded the country in 1940.

Medical Notes in Parliament

A new Session of Parliament was opened on Nov. 11 by the King in person. A passage in the Speech from the Throne said:

> "My Ministers will continue to take all measures open to them to promote the health and well-being of My people in wartime by securing the better care of young children, by the prevention of disease, by the treatment of the sick, and by the alleviation wherever possible of the housing difficulties consequent upon the war."

An effort to improve the conditions of the peoples in the Colonies was also indicated. Proposals for better education in England and Wales and a review of the system of education in Scotland were mentioned.

The debate on the Address extended over the subsequent sittings of the House of Commons. It is hoped that time will be afforded for discussion of an amendment to the Address in the name of Prof. A. V. Hill, which is supported by many medical and lay Members. This proposes to add a declaration that the House, "while recognizing the constructive work done by the Government in building up and maintaining the health of the nation, regrets that further provision is not made for reducing the delay in applying the established results of scientific and medical knowledge to the betterment of public health and efficiency, particularly in regard to the prevention and treatment of venereal disease, the prevention of tuberculosis and other infections by the pasteurization of milk, and the prevention of diphtheria by immunization and through closer attention to factory hygiene and the health and nutrition of young people."

Nurses in Tuberculosis Sanatoria

On Nov. 10 Mr. Wootton-Davies asked the Minister of Health whether, in view of suggestions that girls should be compelled to take up sanatorium nursing and of the effort now being made to increase the number of nurses in sanatoria, he would investigate existing cases where nurses had contracted tuberculosis in the discharge of their duties and were now maintained either by public funds or on a sum which did not permit of adequate and proper care. He also asked what steps were taken to ensure the rehabilitation of nurses who contracted tuberculosis when nursing tuberculous patients. Mr. Ernest Brown called attention to the statement in the recent report of the Medical Research Council, that evidence from research in other countries and expert opinion in our own suggested that the risk of contracting tuberculosis from nursing tuberculosis patients in sanatoria was no greater than that involved in general hospital nursing. He added that a nurse in a tuberculosis institution who contracted the disease was customarily given every care and attention appropriate to her condition by the institution. Arrangements for care and after-care, directed to restoring working capacity, were an essential part of the tuberculosis service and applied to nurses as much as to any other person who had suffered from tuberculosis.

Anti-vaccination Activities

On Nov. 10 Prof. Hill asked the Minister of Health whether he was aware that seven anti-vivisection societies in Great Britain had between them invested capital of about £300,000 and an annual income of about £40,000 which was devoted largely to propaganda, by advertisements and otherwise, against modern scientific methods of preventive medicine; and whether, in view of the fact that eight children on the average died every day of diphtheria alone, he would take steps to counter these activities. Mr. Brown said that local authorities and his Department had for some time been taking steps to counter these societies' activities in regard to immunization against diphtheria by the use of many forms of publicity. This publicity was continuing. In addition he had asked welfare authorities to do their best to relieve health visitors of their non-urgent routine duties, so that they might devote most of their time during the next two or three months to the immunization campaign. The President of the Board of Education had also asked local education authorities and head teachers to use their influence with parents, and to help the campaign in other ways.

Vitamin B_1 of Wheat Berry

The Parliamentary Secretary to the Ministry of Food, in reply to a question by Sir E. Graham-Little, said that his attention had been drawn to remarks made by the Ministry's scientific adviser in his recent Harben Lectures. These included reference to a recent discovery that a large proportion of the vitamin B_1 of wheat germ was contained in the scutellum which formed part of the structure of the germ itself. There was no present intention to modify in any respect the existing instructions to millers regarding the manufacture of national flour.

Air Transport of Wounded

On Nov. 10 Sir Archibald Sinclair informed Mr. D. Adams that in the Middle East, as in other theatres of operations, the evacuation of wounded or sick by air from the battle areas was undertaken by the Royal Air Force. Specially fitted transport aircraft were normally used for the purpose. He was advised by the Secretary of State for War that the supply of drugs and medical equipment from this country and America for the various units of the R.A.M.C. was being fully maintained.

Report of Committee on Nursing Services.—On Nov. 10 Mr. Ernest Brown stated that he was informed by Lord Rushcliffe, chairman of the committee which was inquiring into the conditions of the nursing profession, that while he could not say with certainty when the report of the committee would be available, he hoped, in view of the considerable progress already made, that it would be possible to submit a first report early next year.

The Services

The M.C. has been awarded to Capt. J. Baron, R.A.M.C., and to Capt. A. F. Graham, R.C.A.M.C., in recognition of gallant and distinguished services in the Middle East.

CASUALTIES IN THE MEDICAL SERVICES

Capt. **Ronald Edwin Shaw Lewis**, M.C., R.A.M.C., was killed in action in the Middle East in Oct. He was born on Feb. 15, 1914, the only son of Dr. and Mrs. A. J. Lewis of Birkdale, and was educated at the University of Edinburgh, where he graduated M.B., Ch.B. in 1939. He held a house post at Dover before entering the R.A.M.C. as temp. lieut. in Feb., 1940. He was awarded the M.C. in Aug. last in recognition of gallant and distinguished services in the Middle East. During the first three days of a tank battle he was continuously going to every tank that was hit or set on fire and extricating wounded, many of whom were incapable of helping themselves. The whole of the time he was travelling in a scout car and moving about among tanks. "His devotion to duty and absolute disregard for his own personal safety were magnificent," stated the official citation. He was a member of the B.M.A.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

At a Congregation held on Oct. 31 the degrees of M.B., B.Chir were conferred on R. M. Stuart Matthews.

During October titles of the degrees of M.B., B.Chir. were conferred on G. E. L. Cummins of Newnham College.

UNIVERSITY OF LONDON

The Senate of the University has appointed David Randall Pye, Sc.D., F.R.S., Director of Scientific Research at the Ministry of Aircraft Production, to the post of Provost of University College, London, vacant through the death of Sir Allen Mawer. Dr. Pye will enter upon his duties on Jan. 1, 1943.

UNIVERSITY OF ABERDEEN

The General Council of the University has appointed Robert Richards, M.D.Aberd., F.R.C.S.Ed., lecturer in forensic medicine, to fill a vacancy on the Business Committee.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

At a quarterly meeting of the College, held on Nov. 3, with the President, Dr. Charles McNeil, in the chair, Dr. Wm. George Clark was introduced and took his seat as a Fellow of the College, and Dr. P. A. H. King, D.F.C., Dr. J. G. Sclater, Dr. Adam Patrick, and Dr. J. W. McNee, D.S.O., were elected Fellows. The Hill Pattison-Struthers Bursary in Anatomy and Physiology was awarded to A. Jardine Neil.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

Prof. H. J. Seddon will deliver a lecture on "Recent Work on Peripheral Nerve Injuries" under the auspices of the Dr. John Burns Fund in the hall of the Faculty (242, St. Vincent Street, Glasgow) on Wednesday, Nov. 25, at 4 p.m.

No. 43

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Oct. 31.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1942					1941 (Corresponding Week)

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes paratyphoid A and B for Northern Ireland.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week the outstanding feature was the very large rise of 113 cases in the incidence of dysentery. There was a drop of 73 and 77 in the totals for diphtheria and acute pneumonia respectively.

The southern section of the country was responsible for the decline of 36 in the notifications of scarlet fever. In some of the northern counties there was a decided rise, the largest being 68 in Lancashire.

A small fall in the incidence of diphtheria was fairly general throughout the country, the principal exceptions being increases in Lancashire and Wales of 32 and 22 cases respectively.

Although there were only 9 more cases of measles, there were large variations within the counties. The biggest of the increases were those of Yorks West Riding 178, Flint 67, Glamorgan 62, Surrey 58, Durham 41; and the largest falls those of Derby 90, London 72, Lancashire 55, and Leicestershire 53.

The rise in the incidence of dysentery was accounted for by the outbreak in Caernarvon, where 151 cases were reported in the rural district of Nant Conway. Elsewhere the decline was general, although the outbreaks in the West and North Ridings remained high, with 22 and 28 cases respectively—in the former, cases occurred in six administrative areas; and in the latter all the cases were in Middlesbrough C.B. The outbreak here, which began during the week ending Sept. 19 with 8 cases, has resulted in 153 cases up to the week under review.

In *Scotland* the incidence of diphtheria and scarlet fever remained at a high level, but there were 87 fewer notifications of measles. This decrease was fairly general, the principal exceptions being in the burghs of Glasgow and Kirkcaldy with rises of 12 and 21.

In *Eire* the notifications of diphtheria rose from 76 to 101, the cases being recorded from thirty areas. The 17 cases of acute poliomyelitis constituted the lowest weekly total for seven weeks. Three further cases of typhus were reported from the rural district of Galway, Co. Galway.

Small-pox

Ten further cases of small-pox have occurred in Edinburgh during the week, bringing the total up to 18. The number of persons vaccinated is over 150,000. The danger of the "missed" or "unrecognized" cases of small-pox, arising from a very mild attack, has been stressed by the Chief Medical Officer for the Department of Health for Scotland in a Press appeal to the public.

Returns for the Week Ending November 7

The returns of infectious diseases for England and Wales during the week included: scarlet fever 2,736, whooping-cough 965, diphtheria 881, measles 7,384, acute pneumonia 543, cerebrospinal fever 65, acute poliomyelitis 18, dysentery 142, paratyphoid 6, typhoid 6.

Medical News

Dr. Alexander Edward Gow, F.R.C.P., has been appointed Honorary Physician to the Household of H.R.H. the Duchess of Kent.

Sir J. Donald Pollock, Bt., M.D., LL.D., has been re-elected Rector of Edinburgh University by a very large majority.

A meeting of the Medico-Legal Society will be held at 26, Portland Place, W., on Thursday, Nov. 26, at 4.15 p.m., when Mr D Harcourt Kitchin will read a paper on "Some Legal Aspects of Medical Practice."

At a meeting of the London and Home Counties Region of the Child Health Planning Group on Saturday, Nov. 28, at 2.15 p.m., at 13, Hill Street, Berkeley Square, W., Dr. Margaret Wright will open a discussion on "Strong and Weak Points in the Present Feeding of Children."

The Anglo-Soviet Medical Council is holding a reception in London on Monday, Nov. 23, when Madame Maisky will be presented with *Reviews of British War Medicine* and the Hon. Ivor Montagu will speak on "Scientific and Educational Films in the U.S.S.R."

Health visitors are to be relieved of routine work and instead are to devote their time to securing that all children under 5 are immunized against diphtheria. It is estimated that by this means 80% to 100% of children between 1 and 5 will be immunized before the end of the winter.

The facilities of the Emergency Blood Transfusion Service are to be made available to welfare authorities for maternity cases, provided this does not interfere with the primary work of the service —blood transfusion in war casualties. No charge will be made for fluid given or for apparatus loaned, but welfare authorities will be expected to make their own arrangements for transport and to meet all other expenses. (Ministry of Health Circular 2712)

On Nov. 7 Sir Alexander Macgregor, Medical Officer of Health for Glasgow since 1925, was presented with his portrait in oils in recognition of the knighthood conferred upon him. Dr. R. J. Peters, deputy M.O.H., presided over a large gathering. The portrait, by Mr. W. O. Hutchison, A.R.S.A., was the gift of the members of the staff in the public health department, and it was formally handed over by Col. William C. Gunn, senior assistant M.O.H. In his acknowledgment Sir Alexander Macgregor mentioned that he had been in the department for 37 years, and since he became its head the staff had increased from 1,900 to over 6,000, while the number of hospital beds had multiplied fivefold. He hoped that after the war the department would not be subjected to excessive organization. In their work they came into contact with the daily life of citizens, and he did not want any red tape connected with it.

The Silver Thimble Fund is appealing for help in endowing a ward of ten beds in a Malta hospital; it costs £1,000 to endow and name one bed. This fund has already done much for the sick and wounded (a similarly named fund raised £60,467 in the last war), and it asks for donations and/or old silver thimbles, any broken and unwanted silver or gold trinkets, etc., which should be sent to the fund at 17, High Street, Wimbledon Common, S.W.19.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, London, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

Telephone No.—B.M.A. and *B.M.J.*: EUSTON 2111.

Telegraphic Addresses.—EDITOR, *Aitiology Westcent, London*; SECRETARY, *Medisecra Westcent, London*.

B.M.A. Scottish Office: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Reconditioning of Corks

R. B. writes: In reply to Dr. C. Heap (Oct. 31, p. 534), the following process produces corks quite fit to use. I keep an old calico bag hanging in my dispensary (a bag in which one used to buy 7 lb. of dog biscuits), and in this used corks are collected as they are handed back. When the bag is about three-quarters full a blob of soft soap, or a small lump of ordinary soap, or a handful of soap flakes or powder is put in and the neck of the bag tied with a piece of string. The corks must not be tightly packed but loose enough to allow plenty of movement and friction. The bag is then immersed in a basin of hot water and thoroughly rubbed and pounded and worked about. Dr. Heap will be surprised at the amount of dirt which comes out, for one or two fresh lots of water are needed before colour ceases to come out of the bag. The bag is then hung up to drain and the corks can later be dried on a newspaper in the sun and will be of a uniform light brown colour, fit to use. If it is desired to make the corks a little paler they can be tipped into a bowl or jar and left for some hours with some hydrogen peroxide, which is stirred up or shaken up over them occasionally to keep them moist. I dare say a stronger bleaching agent could be used, but then the corks would need washing again afterwards.

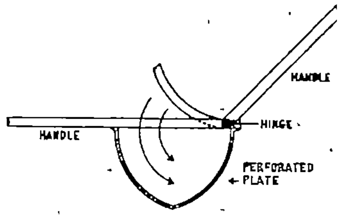
Dr. M. E. Lampard (Colchester) writes: In reply to Dr. C. Heap's inquiry, it is possible to bleach corks by soaking them in very weak hydrochloric acid.

"X. Y." writes: Greasy corks must be treated with a suitable solvent first. For corks which are not greasy the following method bleaches and cleans them satisfactorily. Soak in 10% hydrochloric acid for half an hour, then immerse for another half-hour in a solution of sodium hyposulphite acidified with hydrochloric acid. Finally wash in soda and water.

LETTERS, NOTES, ETC.

Device for Making Fomentations

Dr. Geoffrey G. Airey (Ledbury) writes: I have recently be using a device for the preparation of hot fomentations which m be of interest to some of your readers. It eliminates a great de of the trouble in preparing this type of dressing and saves time, as well as material and the nurses' hands. The material saved is, of course, the towel containing the dressing, as that nearly always gets into the flame of the gas burner. The device is nothing more romantic than the ordinary domestic potato-masher, as shov in the illustration. Where many of these dressings ha to be done daily there is a great saving of time. The li is, of course, put into the cage of the masher, which is immers in the boiling water.



Treatment of Impetigo

Dr. T. Pires writes from Burnham-on-Sea: I would like to endor Dr. Simpson Smith's findings (Nov. 7, p. 560) in the treatment impetigo with liq. ferri perchlor. fort. The application can made over scabs. The infection is arrested and the period of infe tivity considerably shortened, the normal skin being in no w affected. In the case of persistent scabs applications should renewed when a hyperaemic condition develops, "washing off the scab, as it were. In some cases where a ring of "roll edge" persists after the scab falls off, this should be paint round with liq. ferri perchlor. solution. The effectiveness of t method commends it even more than the saving of expenditure.

Roche Products Limited, Welwyn Garden City, Herts, have pu lished a second edition of their pamphlet *Vitamins in Medic Practice*. The text has been enlarged and new illustrations adde In accordance with the Paper Control Regulations a charge of 9 a copy is made; all the money collected in this way will be s aside for one or two medical charities or the Red Cross.

MEDICINE 100 YEARS AGO

Extracts from a leading article in the *Provincial Medical Journ* of November 19, 1842 (the forerunner of the *British Medic Journal*):

"The poor-law commissioners have recently published, throug the medium of their secretary, Mr. Chadwick, a very elabora report on the sanatory condition of the laboring population Great Britain. It might fairly be asked, *in limine*, how the directio of so difficult and complex an investigation was entrusted to a gentl man completely ignorant of the subject submitted to his inquir how a poor-law secretary—unacquainted with the most simple la of the human economy, and possessing not a particle of that pr liminary knowledge which is essentially necessary to every o commencing a special investigation—should take upon himself examine facts and form conclusions connected with the publ health. Such, however, has been the case; and as 'her Majesty principal Secretary of State for the Home Department' has thoug fit to select Mr. Chadwick for the purpose of inquiring into t sanatory condition of the people, we shall endeavour, as loy subjects, to regard the selection as a fitting one, and to pay all d deference to opinions which emanate from so high an authority.

"Our ideas of fitness and the promptings of common sense a indeed, wonderfully disturbed by the appearance of Mr. Chadwi as an authority on hygiene; and the necessity of noticing his repo places us in the awkward position condemned by the proverb, endeavouring to 'make a silk purse of a ——' etc.; but to th necessity we submit, because we must take Mr. Chadwick's report have no report at all. This conclusion is inevitable. The poo law commissioners have resolved, *inter alia*, on seizing by anticip tion on the duties of a board of health, on constituting themselv into a council for the regulation of all matters connected wi public hygiene; and the present report is evidently put forth as feeler upon this matter. To have entrusted the report to a medical man, or any body of medical practitioners, would not ha suited the views of the commissioners; they accordingly forced the secretary upon Lord John Russell, employed themselves diligent in the collection of a vast body of facts, and now come before t public and the government with an official report on the causes a prevention of disease amongst the laboring classes.

"The observations which we have just made are rather address to the source whence Mr. Chadwick's report has emanated than the report itself, which, on the whole, is creditable to the indust of its author."

THE OUTBREAK OF SMALL-POX IN GLASGOW, 1942

BY

Sir ALEXANDER MACGREGOR, M.D.
Medical Officer of Health

AND

ROBERT J. PETERS, M.D.
Senior Deputy Medical Officer of Health
Glasgow

The following is an account of the main features of the outbreak of small-pox which occurred in Glasgow during June and July. The total number of cases diagnosed as small-pox was 36, of which 8 were fatal. The outbreak consisted of two groups of cases. The first, or "ship" group, numbered 11 cases among the passengers and crew of a ship which arrived from the East at the Port of Glasgow on May 29. The second, or "city" group, consisted of 25 cases among the general population. Direct connexion between these two groups was never demonstrated. Tables I and II give details of the cases as to onset and vaccination state.

The "Ship" Cases

Of the 11 cases 8 were members of the crew, 2 were passengers, and 1 was a boarding medical officer. The ship took passengers on board at Bombay, and when it reached Glasgow on May 29 a member of the crew (Case 1), an electrical engineer, was found to have confluent small-pox. His rash had developed on May 24 and he had been treated in his cabin. The diagnosis was not made till his arrival in Glasgow, so that for at least 8 days he was infectious and not under strict isolation. The subsequent cases consisted of 7 members of the crew who developed their disease while under surveillance on the ship, 2 passengers—one a Polish officer who sickened in a billet in Fifeshire, and the other a baby of 11 months who was taken ill in Swindon, also while under surveillance—and one of the boarding medical officers who took part in the inspection and vaccination of passengers and crew on May 29. The source of Case 1 was never discovered. This patient might have been infected while ashore at Capetown or he might have been infected from a "missed" case on board.

TABLE I.—*Small-pox—Glasgow, 1942: Ship Cases*

Case No.	Age and Sex	Occupation	Date of Rash	Type* of Rash	Previous Vaccinations (showing Ages)	Recent Vaccination and Result	Remarks
1	28 M	Electrical engineer	24/5	C.	Nil ?	—	Died 2/6
2	21 M	Engineer	7/6	S.M.	Nil	29/5+	
3	23 M	Engineer	7/6	D.M.	,,	29/5+	
4	23 M	Assistant cook	9/6	C.	,,	29/5+	Died 15/6
5	17 M	A.B.	11/6	S.M.	,,	29/5+	
6	19 M	A.B.	12/6	D.M.	,,	29/5+	
7	20 M	Steward	15/6	D.	,,	29/5−	
8	23 M	Quartermaster	23/6	S.M.	,,	29/5− 11/6+	
9	23 M	Passenger	9/6	S.M.	1, 7, 14 years	29/5+	
10	11/12 M	Passenger	9/6	D.	Nil	29/5−	Swindon case
11	34 M	Medical officer	13/6	SC.	Infancy	29/5−	

* S.—Sparse; D.—Discrete; SC.—Semi-confluent; C.—Confluent; M.—Modified.

Two members of the crew died of confluent small-pox (Cases 1 and 4). The remaining cases were mostly relatively mild, the disease being considerably modified by vaccination. Indeed, 4 had only a few spots and practically no constitutional symptoms.

Measures Taken on Ship's Arrival.—When the vessel reached Glasgow, the passengers, numbering 1,039, and the crew, numbering 201, were detained on board till the following day in order to permit medical inspection and vaccination to be carried out. No other case or suspected case was discovered. Arrangements for surveillance of passengers and crew leaving the ship were made in accordance with the provisions of the Port Sanitary Regulations, and disinfection of the infected crew's quarters and other selected sections of the ship was carried out with some thoroughness. A daily medical inspection of crew remaining by the ship was instituted, and, after secondary cases began to occur, vaccination and inspection of all workmen on board were undertaken as additional precautions. During the week following arrival, several of the crew were admitted to hospital for observation for various intercurrent illnesses, including some severe vaccinial reactions. These reactions, occurring as they did at the end of the possible incubation period of small-pox, complicated the problem of diagnosis for the medical inspectors, whose duty it was to see that cases were removed at the very earliest stage of infectivity.

Transmission of Infection on Board.—The incidence of small-pox among the crew and passengers provided instances of both direct and indirect transmission of infection. The engineers, among whom the infection originated, had their own separate quarters, mess-room, and pantry on the main deck. Apart from the initial case of small-pox, ill in his cabin from May 24 to 29, there were 15 engineers, of whom 9 had been vaccinated in 1940, 1 in 1918, and 1 in 1920, while 4 were unvaccinated. Two of these (Cases 2 and 3) contracted small-pox. The infection also passed to 4 other members of the crew—namely, an assistant cook, two seamen, and a quartermaster. Two passengers—the Polish officer and the baby of 11 months—were also infected. An electrical engineer who occupied the same cabin as the original patient up to May 24, and who attended to him during his illness, had had occasion to repair a potato-peeling machine with the help of the assistant cook, an unvaccinated South Sea Islander (Case 4). The latter developed a small-pox eruption on June 9. It is probable that the other cases were infected in somewhat the same manner by an intermediary or by some infected article in common use. The facts indicated that the disease was not only severe but highly infectious. The majority of the crew had been vaccinated in 1940, but the ship had also a complement of 37 unvaccinated members recruited since then, and they alone among the ship's company were involved in the outbreak. It is also a proper inference that, had these men been vaccinated when the ship left Bombay, the outbreak of small-pox would not have occurred. It is difficult to understand why this common-sense precaution was not taken.

Incidence in Relation to Vaccination.—The secondary cases must have contracted the infection during the last few days of the voyage, when the first case was in its most infectious stage. The vaccinations performed on May 29 did not fully protect them. As regards the earlier cases, the period which elapsed between the date of successful vaccination (with good result) and the onset of the rash was as follows: 9 days in Cases 2 and 3; 11 days in Case 4 (the fatal case); 13 days in Case 5; and 14 days in Case 6. In other words, they were vaccinated on the first to the fifth days of the incubation period. This result, in so many cases, was unexpected, being contrary to the general experience that a better measure of protection should have accrued from successful vaccination performed within the first week of the incubation period, certainly within the first day or two. The vaccination of Case 7 did not take; Case 8 was also negative, but in this instance the rash appeared 12 days after a second and successful vaccination. The rash in Case 9 appeared 11 days after successful vaccination; in Case 10 (the infant) primary vaccination failed to take; the medical officer (Case 11) had been vaccinated in infancy, but his vaccination on May 29 was unsuccessful.

The Practice of Vaccination in the Outbreak.—Cases 1 and 4 showed that the infection was of a virulent type, and it was apparent in other cases that immunity from successful vaccination was not developing rapidly enough to afford complete protection. In an attempt to secure better protection the single-stroke technique was discarded and an insertion consisting of three incisions 3/8 in. long and 1/8 in. apart was adopted as the standard practice throughout the remainder of the outbreak. A single unsuccessful vaccination was not accepted as evidence of immunity in the absence of a history of recent vaccination, and therefore it was decided to re-vaccinate such cases after four days, particular care in this respect being taken in the case of close contacts, hospital staffs, and patients. In very close contacts three separate insertions as above described were made.

The "City" Cases

There were in all 25 cases of small-pox in the city group, 6 of them fatal. Two patients are included who were taken ill while away from home. The course of the outbreak is shown in the following table according to the dates when the patients were recognized to have small-pox and admitted to hospital:

	June					July							Total
	26	27	28	29	30	1	2	3	9	10	20	31	
Primary cases ..	1	4	3	5	1	2	1	1	–	1	2	–	21
Secondary cases	–	–	–	–	–	–	–	–	2	1	–	1	4

The 21 primary cases had no association with each other, nor was their infection traced to its source. The 4 secondary cases were direct contacts and had been under observation as such. As each case occurred, the close contacts were isolated for observation in a reception-house, part of two fever hospitals being used for this purpose. Work and school contacts, along with neighbours for some distance round, were offered vaccination and watched for 17 days, with the object of placing a cordon of protected persons round each new focus of infection as it showed itself. But early in the outbreak there were convincing indications that these routine precautions would in all likelihood prove insufficient to prevent the spread of the disease, which was of a virulent and infectious character. The first city case was admitted to hospital on June 26, and on the 27th 4 more were diagnosed. Four cases followed on the 28th and five on the 29th. Thus in four days 13 cases, of which 7 were confluent, came to light. They occurred in widely separated areas in the north, east, and south-east of the city, and there was no evidence whatever of connexion between them.

The position, then, on Sunday, June 28, was that cases of severe small-pox were occurring in quick succession in different parts of the city, affecting adults and children alike, without any source or sources of infection that could be traced. It was therefore felt that it would be taking too great a risk to rely solely on routine measures to prevent the disease from assuming epidemic proportions, and that a situation had arisen serious enough to justify the adoption of further precautions to meet it. It was appreciated also that the danger of wide dissemination of the infection was enhanced by free movement of the population throughout the country in time of war, and was likely to be increased further during the approaching holiday season in July. Another consideration was the injury to war production which an epidemic of small-pox would be certain to cause. The strongest argument, however, was supplied by past experience, which taught that epidemics tended to linger for long periods. Examples of this occurred in Glasgow in 1900-1 and in 1920, as well as in the epidemics of last century. Accordingly it was decided to set up, without delay, facilities for general vaccination, and to enlist the support of medical practitioners, to whom a circular letter was sent on the same day (June 28), apprising them of the facts and of the method of vaccination recommended. During the next two days 25 schools were selected as vaccination stations, and a staff of medical practitioners and medical students engaged and allocated, along with child welfare medical officers, school medical officers, and hospital residents. The assistance of nurses from among health visitors, school nurses, and sisters attached to first-aid posts was obtained. Clerical staff and helpers were supplied by volunteers from the Civil Defence Casualty Service to reinforce those of the Health Department. Supplies of lymph were obtained, publicity and posters arranged for, and instructions issued on the method of vaccination to be employed. A payment to medical practitioners of 2s. 6d. for each person vaccinated in their consulting-rooms and practices under the scheme was approved. Lymph was issued free of charge.

TABLE II.—*Small-pox—Glasgow, 1942: City Cases*

* S.=Sparse; D=Discrete; SC.=Semi-confluent; C.=Confluent; H.=Haemorrhagic; M.=Modified.

By Wednesday, July 1, the arrangements were complete. On the first day 33,000 persons were vaccinated at the centres. During the first week 282,255 vaccinations were performed, during the second week 90,375, during the third week 5,246, and during the fourth week 439—a total of 378,315. A large number of vaccinations were performed by medical practitioners in private and by arrangement at works, factories, warehouses, and offices. It is estimated that approximately half a million persons submitted themselves to vaccination within a month.

Vaccinial rashes were unusually frequent and were of great variety. A special report is in preparation on this subject. The papular type of eruption was a source of some administrative difficulty, as it sometimes had sufficient resemblance to small-pox to justify admission of the patient to hospital for observation. Chicken-pox was very prevalent at the time, and in some cases the character and distribution of the eruption created an element of doubt as to the true diagnosis.

Vaccination History of the Patients.—There were 8 patients who had not been previously vaccinated; 2 of them died. Eleven patients had been vaccinated in infancy, and there was one who had had his primary vaccination in 1917, their ages varying from 13 to 77; 3 of these died, their ages being 20, 65, and 72 respectively. A group of 5 patients had had their primary vaccination in infancy and had been vaccinated later—one in 1910 and 1920, two in 1920, one in 1929, and one in 1940 without success. This last patient (Case 6), a woman of 37, was again revaccinated unsuccessfully on June 2; she contracted small-pox three weeks later and died. Thus the city patients who sickened of small-pox were either unvaccinated or had not been vaccinated or revaccinated successfully for upwards of 13 years prior to the present outbreak. Among these 25 cases 4 were contacts and had been vaccinated accordingly, with successful reactions. Their eruptions appeared from 9 to 12 days later, an experience similar to that already met with in those members of the crew who had been vaccinated successfully during the early days of the incubation period.

No link between the ship cases and the city cases was ever discovered in spite of the most careful search. It is possible that the city cases were infected from an independent source, such as a missed case from another ship from the East; but as there was no evidence of any such origin it must be presumed that they received their infection from the ship either directly or indirectly in some unknown manner. The occurrence of a group of cases in separate districts of the city, all infected within a few days of each other, suggests the presence of a mild unrecognized case as the most likely cause. Case 23, for example, had not been outside the mental hospital, of which he was an inmate, for some years, and he had had no visitors and no parcels during the weeks preceding his illness. All visitors to the hospital were checked up, with completely negative results.

Past Outbreaks of Small-pox

Major outbreaks of small-pox in the past have always been protracted. That of 1920 was introduced from the East in February, lasted till November, and was at its height in May, June, and July, amounting to 542 cases, with 113 deaths. The invasion of 1900 caused 397 cases between April and December, with its peak in June and July; this was followed in 1901 by a severe outbreak with 1,389 cases, which was again succeeded by a recrudescence in 1901-2, with 469 cases. Still earlier there was a large epidemic which lasted from 1871 to 1874, and sharp outbreaks occurred in Scotland and Glasgow in 1893, 1894, 1895, and 1897. In the bigger outbreaks, general vaccination was practised mostly by house-to-house visitation. In 1920, when centres were also set up, 225,000 persons were vaccinated during the several months when the outbreak was at its height. The present experience is in strong contrast; and it may be said that the people themselves, by taking timely advantage of the advice given and the facilities provided, stopped the outbreak at its start.

Lessons of the Outbreak

It is apparent from the above description that complete reliance cannot be placed upon vaccination unless performed successfully before the date of exposure. Also, immunity from vaccination diminishes after a few years. These two facts render it essential that everything possible should be done to protect ships' crews and passengers sailing from the East. Prevention of the spread of infection depends on the success of the two principal prescribed measures—vaccination and subsequent surveillance. If vaccination is not carried out promptly, surveillance becomes a matter of great importance; but adequate surveillance of contacts is more difficult to exercise in time of war because the destinations of passengers and crew are more uncertain, and may, in fact, be merely temporary or accommodation addresses. Had the case on board been accurately diagnosed and precautions taken, the subsequent story would have been very different. It would have been still better had vaccination of the susceptible members of the crew and passengers been carried out when the ship left Bombay, a port known to be infected. Attention to the vaccination of all who sail from Eastern ports, both passengers and crews, should be enforced as a routine precaution; otherwise there is grave danger of small-pox being introduced into this country. In the case of passengers, this would mean vaccination of those who had not been recently protected, as a condition of travel. In the case of crews, it would require the co-operation of members of the Merchant Navy, the great majority of whom would no doubt be willing to be vaccinated from time to time if the need for such a precaution were made clear to them. Even the most careful attention to the provisions of the Port Sanitary Regulations, including conscientious surveillance of crew and passengers after arrival in this country, leaves loopholes for the entry of small-pox. Therefore adequate vaccination of all who travel from infected places is the only true safeguard.

WAR SURGERY OF THE EYE

REMOVAL OF MAGNETIC INTRA-OCULAR FOREIGN BODIES BY THE POSTERIOR ROUTE

BY

H. B. STALLARD, M.B.E., M.A., M.D., F.R.C.S.

Assistant Eye Surgeon, St. Bartholomew's Hospital; Major, R.A.M.C.(T.A.)

Intra-ocular foreign bodies possessing magnetic properties may be removed by one of two routes: (1) The anterior route, in which the foreign body is attracted forwards by a giant electro-magnet, through the suspensory ligament into the posterior chamber, then, by changing the direction of the magnetic force, is drawn between the iris and lens into the pupil and anterior chamber, whence it is extracted from the eye through a keratome section by a small electro-magnet guided by the operator's hand. (2) The posterior route, which necessitates exposure of the sclera by turning back a conjunctival flap either at some site of election or over the penetrating wound in this structure, if such is obvious or unclosed. An incision is made through the sclera, and the entry wound is enlarged to a size just adequate for the extraction of the foreign body. A magnet terminal is placed into the lips of the scleral wound.

Advantages of the Posterior Route

The advantages of this method of extracting intra-ocular foreign bodies, caused by the fragmentation of war missiles, are several. These bodies are rough irregular pieces, which if drawn forward by the giant electro-magnet in the anterior-route technique of extraction would inevitably damage the ciliary body and iris and might also injure the lens. The metals which compose the casing of shells, grenades, mines, and booby-traps are alloys with either low magnetic properties or none at all. In many instances it is essential to place the giant magnet terminal as near to the foreign body as possible on account of its low magnetic properties.

It happened by chance that all the penetrating wounds of the eye treated at the Scottish General Hospital during the Western Desert battles from Nov., 1941, to Aug., 1942, associated with a metallic magnetic intra-ocular foreign body, had the wound of entry through the sclera, and 80% of these were in the lower temporal quadrant in front of the equator, the lens being undamaged. The point of this is that exploration of the entry wound, its toilet, and closure are generally necessary, and it seems reasonable to save further surgical intervention by using the entry wound for the exit of the foreign body. However, in some cases, particularly high-velocity fragments of 2.5 mm. diameter and under from aerial bombs, the scleral wound had healed without complication during delayed transit through a field ambulance and casualty clearing station. In such cases a scleral incision of appropriate length was made at a site of election.

Another advantage of the posterior route is that in cases in which the foreign body proves to be non-magnetic the opening may be used for the passage of an instrument such as a thin pair of straight iris forceps or a fine wire snare placed in the lumen of a hypodermic needle (Brigadier C. W. Graham's technique), with which, under ophthalmoscopic view, the foreign body is seized and extracted. This was done successfully in the case of Corporal B., in which a 2 by 2 by 1 mm. rectangular fragment of a Breda shell detonator cap had penetrated the sclera in the lower nasal quadrant about 2 mm. in front of the equator, and after tearing a ragged hole in the retina lay in the vitreous in the upper nasal quadrant behind the equator. It seems that the posterior-route operation disturbs an eye less than the anterior-route procedure does. After the former operation the eye regains its normal appearance more quickly, and ciliary injection is certainly not increased, as is sometimes the case after the anterior-route extraction.

Procedure in the Western Desert

The foreign bodies were ragged-shaped pieces of metal with rough granular surfaces. Their size varied from 3.5 by 2 by 0.5 mm. to 1.5 by 1 by 1 mm. Some were cubes 2.5 by 2.5 by 2.5 mm. or slightly less than this, but the majority were rectangular flakes, with an average thickness of 1 mm. They consisted of fragments of shells, air-cannon shells, and bombs in equal incidence. In no case was there any associated gross intra-ocular infection, and in only one was there a clot of opaque yellow fibrin adherent to the foreign body on extraction. It is doubtful whether the administration of sulphonamides at irregular intervals during evacuation from the forward areas could have played an appreciable part in the prevention of infection during the 6 to 14 days taken in evacuating men in the 8th Army's advance to Benghazi in Nov. and Dec., 1941. In the withdrawal into Egypt in June, 1942, as the enemy advanced, the wounded arrived at progressively shorter intervals of time after being hit, and at one period they came straight from the battlefield, circumventing field ambulances and casualty clearing stations, and were operated upon within 12 hours of being wounded. The delay of 6 to 14 days in giving appropriate surgical treatment to those hit in the early phases of the campaign did not seem to have jeopardized the future safety of the eye.

In a few instances the battalion and field ambulance medical officers, aware of the dangers of vitreous loss, had ordered the evacuation of these wounded lying on stretchers. The majority walked to aid posts and were then transported as sitting cases. Two of these sitting cases arrived with a vitreous herniation through the wound. The bead of vitreous was 2.5 mm. in diameter in wounds about 3.5 mm. long, and it was covered with conjunctiva and surrounded by adhesions to Tenon's capsule and the episcleral tissues.

It is difficult to assess the protective value, if any, of the British steel helmet so far as the eyes are concerned. Some men were wearing their steel helmets when hit and others were not. No useful deduction could be made from these data in relation to the possible direction of the missile which struck the eye. Major P. B. Ascroft (O.C. Mobile Neurosurgical Unit) has prepared a composite photograph based on a radiograph of a soldier's skull when wearing in turn a British and an Italian steel helmet. On this radiograph he marked the sites of 150 penetrating wounds of the skull. Of these, 65 fell below the level of the British helmet but were covered by the Italian helmet. From this radiograph it seemed likely that the Italian helmet would protect the eyes from metal splinters flying from an angle of 90 degrees over on either side. There was a remarkable concentration of wounds about the frontal area.

Investigation of Cases

The soldier is asked about the position of his head when wounded and the direction from which the missile came. Information about this latter is often unreliable. When there is an associated head injury the soldier generally has no recollection of being hit. In a few cases such facts as the above are helpful in tracing the probable course of the missile. The position of lid injuries may assist in this respect but is sometimes deceptive.

The nature of the missile is important. Fragments of shells and bombs are generally magnetic, some in low degree. Italian hand grenades, booby-traps, and land mines are composed of non-magnetic alloys the fragments of which are about 1 mm. thick. Some booby-traps are made of bakelite, which is not radio-opaque and is non-magnetic. Such a fragment was extracted from an eye with forceps under direct view. In the case of land-mine, hand-grenade, and booby-trap explosions the wounds are generally multiple and, except for such serious injuries as traumatic amputation of one hand and multiple penetrating wounds of one or both eyes, are superficial. Fragments of metal may readily be taken from the skin and tested for radio-opaque and magnetic properties.

In all cases except one—that of a sepoy with both eyes penetrated by aerial-bomb fragments—the entry wound was evident. The conjunctival wound showed localized hyperaemia, and in all cases of over one day from the time of wounding it was closed and the conjunctiva was adherent to the episcleral tissues and sclera around the site of the wound. In 50% the intra-ocular foreign body was seen with the ophthalmoscope, but in the remainder vitreous haemorrhage obscured its position. In the latter, *x*-ray location was done.

Location of Foreign Body by X Rays

Brigadier C. W. Graham has introduced a simple technique which, in the absence of elaborate *x*-ray apparatus, is of practical value. It is as follows: The eye is anaesthetized with cocaine, and when much inflamed 2 or 3 minims of novutox is injected into the episcleral tissues at the limbus at 12, 9, and 3 o'clock. A silver ring of a size to fit exactly the corneo-scleral junction is stitched in position by sutures of 000 silk passing through the conjunctiva at 12, 9, and 3 o'clock respectively. A drop of paroleine is instilled into the eye, and a pad moistened in the oil is applied to the closed lids and bandaged in position. When possible the patient sits during *x*-ray examination. In some cases other wounds prevent this. During the first exposure he is directed to look with his uncovered eye forwards and for the second to look downwards. For this purpose conspicuous marks such as red disks or lights 5 cm. in diameter are placed on the wall for sitting cases and on the ceiling for lying cases at the two points in which fixation of the eyes is necessary during exposure. Each exposure is half the normal. To obtain a postero-anterior view of the orbit free from the dense shadow of the petrous part of the temporal bone the head is tilted slightly so that the occiput is down and the face up; the petrous shadow then falls over the antra. In an accurate postero-anterior radiograph the silver ring shows as a perfect circle, and in the lateral as a linear shadow.

Interpretation of Radiographs

The diameter of the silver ring is known and its measurement is checked on the *x*-ray film. Any radiographic magnification is noted. This has never been more than 1 mm., and, when present, allowance must be made for this fact. When an anode film distance of 30 in. or more is used, parallactic magnification of the ring is negligible and a schematic eye of 24 mm. drawn on the film is accurate enough. In the lateral view a line is drawn posteriorly from the centre of the ring and at right angles to it for about 22 mm. The upper and lower limits of the ring are used in turn as the centre of a circle whose radius is 12 mm. (e.g., half the average length of an eye—24 mm.); with a pair of dividers set at 12 mm. the horizontal line is intersected by arcs described from the above centres. The point of intersection on the horizontal line is now taken as the centre of a circle with 12 mm. radius, and this is described on the radiograph. A similar procedure may be carried out with the silver ring in the second position—that is, looking down. Likewise in the postero-anterior view, a circle of 12 mm. radius is described round the centre of the silver ring. The ring is known to be at the limbus, and so measurements may be taken from this on both the postero-anterior and the lateral radiographs.

Movement of the foreign body is the essential diagnostic feature. If the relation of the silver-ring image to the foreign body is unaltered in the first and second positions it may be presumed that the foreign body is moving with the eye. The radiographs with the schematic eye marked upon them will indicate also the position of the object with regard to the centre of rotation. If the foreign body is in front of this it will apparently move with the ring; if behind, against it—that is, a foreign body in the posterior half of the eye will lie at a higher level in the second position where the ring has rotated downwards.

The shadow of the foreign body might fall within the circles described and yet be outside the eye. This point is settled by the movement of the foreign body, which is absent when it is extra-ocular. There is, however, an exception to this in the case of a foreign body in Tenon's capsule, where slight movement may take place, but this is rarely as great as in the case of an intra-ocular foreign body. In such cases, therefore, if the foreign body shows a new relation to the ring in the second position it is probably outside the eye. When the foreign body is clearly outside the limit of the circles described it is certainly extra-ocular. The size of the foreign body is carefully measured on the radiograph. This will determine the length of the scleral incision necessary for its extraction.

Operation

Anaesthesia.—(1) Surface. Cocaine 4%, 4 drops (the only suitable anaesthetic available). (2) Infiltration. 0.5 c.cm. of novutox 3% with 3 minims of 1 in 1,000 adrenaline may also be injected into the bellies of adjacent rectus muscles when traction is likely to be made on these. In cases of considerable ocular injection 1 c.cm. is also injected into the region of the ciliary ganglion. Anaesthesia has been adequate in all cases.

Incision.—With spring scissors a curved incision is made in the conjunctiva anterior to the area of sclera to be exposed, so as to fashion a flap with its convexity forwards. This is undermined down to the sclera so that it consists of conjunctiva, Tenon's capsule, and episcleral tissue. Two sutures of 000 silk are inserted 2 mm. behind the free edge of the flap, which is now reflected posteriorly and secured thus by clamping the sutures to the head-drapings. Care must be taken in separating adhesions around the site of a scleral wound. The overlying conjunctival wound is generally healed, and in most cases the conjunctiva can be dissected off intact. In two cases there was a prolapse of intra-ocular contents, making a knuckle about 2.5 mm. high by 2.5 mm. at its base. In such cases the covering of episcleral tissue and adhesions was left untouched until after diathermy had been applied and a scleral suture inserted. Then the prolapse and its coverings were cut off flush with the sclera.

After reflecting the conjunctival flap the sclera is swabbed and any bleeding-point arrested by touching it with a fine probe heated in a flame. Traction on the globe may be effected either by a scleral hook or by passing sutures of No. 1 white silk through the tendon of a rectus muscle or by seizing the tendon with fixation forceps (Fig. 1). If the scleral wound is either over the posterior part of the pars plana of the ciliary body or between the ora serrata and the equator one or two applications of surface diathermy, 70 to 80 mA for 5 seconds, are made over the wound so as to extend just beyond its limits. This effects contraction and hardening of the sclera and incidentally reduces the size of the wound. Its purpose is to produce haemostasis in the sclera and underlying uveal tract and to ensure subsequent choroidal retinal adhesions where the foreign body tears these membranes on leaving the eye. Then a mattress suture is passed through the thickness of the outer half of the sclera, which it traverses 1.5 mm. from and parallel to the edges of the wound for a distance of 2 mm. (Fig. 2). For this purpose Merson (Edinburgh) made for me a small eyeless needle threaded with 000 silk. Generally one suture is sufficient, but two may be necessary in larger wounds. The loop and ends are placed clear of the scleral wound.

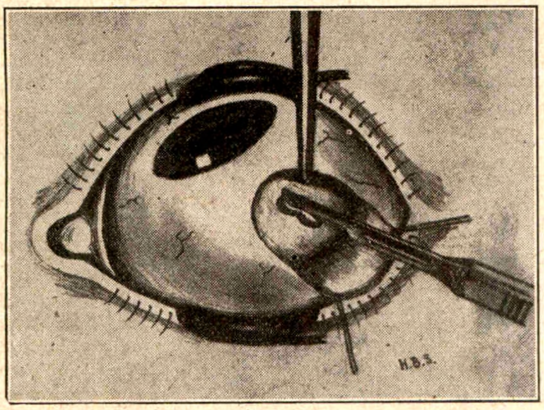

FIG. 1.—A flap of conjunctiva, episcleral tissue, and Tenon's capsule is reflected in the lower temporal quadrant. Fixation forceps are applied to the tendon of the external rectus muscle. A No. 15 Bard-Parker knife incises the sclera where two applications of surface diathermy have been made.

The wound is now enlarged to a size 1 mm. greater than the maximum diameter of the foreign body as measured on the radiograph. This is done by cutting the sclera with a No. 15 Bard-Parker blade kept on the sclera and run gently to and fro for 2 to 4 mm. as required. All but the deepest layers of the sclera are divided in this manner. The head and eye are then turned so that the scleral wound lies uppermost, thus by gravity minimizing the risk of vitreous loss. Fine hooks are now inserted into the edges of the scleral wound and are drawn apart. The uvea shows through the remaining layers of the sclera, which are now cut with the point of a cataract knife (Fig. 2).

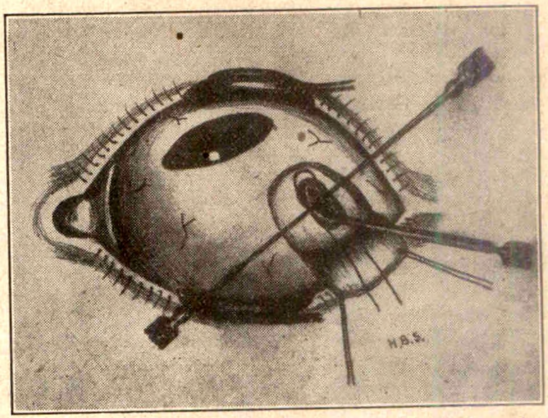

FIG. 2.—A mattress suture has been inserted through the superficial layers of the sclera. Fine hooks retract the edges of the scleral wound, whilst a cataract knife completes the incision through the deeper layers of the sclera to expose the uveal tract.

The procedure is similar in cases in which the scleral wound has healed or is not evident, the scleral incision being made at some site of election. The only difference is that the incision is made through about half the thickness of the sclera and then the mattress suture is inserted. With effective diathermy there is no bleeding.

The Mellinger giant electro-magnet is now swung into position, and the terminal introduced into the lips of the wound. A "click" is heard as the foreign body strikes the terminal, which is then removed. The mattress suture is now seized with Arruga's capsule forceps and drawn upon, thus closing the lips of the scleral wound. It is then tied. Any traction sutures in the rectus muscles are now cut and removed. The conjunctival flap is replaced and the conjunctival incision closed by a continuous key-pattern suture of 000 black silk. Ung. atropin. 1% is inserted on a glass rod swept beneath the upper lid at the outer canthus. A pad moistened with paroleine is applied over the closed lids and secured by a bandage.

To date, vitreous loss has never occurred and the eyes have shown no post-operative exacerbation of inflammation.

Summary

The reasons for removing by the posterior route intra-ocular magnetic foreign bodies due to war missiles are discussed. The investigation of a case, a simple method of x-ray location of intra-ocular foreign bodies, and the operative technique of extraction are described.

Major W. H. Milligan, x-ray specialist (Scottish) General Hospital, has devoted much skill, care, and patience to the location of intra-ocular foreign bodies. I thank him for his admirable work and invaluable help and advice in this respect. I also thank Brigadier C. W. Graham, Consulting Ophthalmologist, M.E., and Colonel H. D. F. Brand, O.C. Scottish General Hospital, for permission to publish this paper.

There have been numerous reports in the American medical press during the past year on the formation of sulphonamide crystals in the renal tubules. In one of these (*J. Urol.*, 1942, **47**, 258), H. R. Newman and I. H. Shleser point out that there is the less-recognized risk of the formation of putty-like renal calculi. They record a case where, two years after the administration of sulphapyridine and prontylin, renal calculi were found on x-ray examination to be in the pelvis of the right kidney, and were removed. They crumbled easily on slight pressure, and chemical analysis showed the presence of large quantities of sulphonamide intermixed with protein and some magnesium, ammonium phosphate, and a trace of calcium carbonate.

LONG SURVIVAL AFTER TOTAL GASTRECTOMY

A BRIEF REVIEW, WITH A REPORT OF TWO CASES

BY

CECIL A. JOLL, M.S., F.R.C.S.

Senior Surgeon, Royal Free Hospital, Royal Cancer Hospital, and Miller General Hospital

AND

D. I. ADLER, F.R.C.S.Ed.

Lately Surgical Registrar, Royal Free Hospital

Despite the frequency of carcinoma of the stomach the number of recorded total gastrectomies is still insignificant, and few in relation to the large number of partial gastrectomies. Thus Livingston and Pack (1939), in their admirable monograph on carcinoma of the stomach covering over 14,000 partial gastrectomies, make no mention of total gastrectomy in the treatment of carcinoma ventriculi, and at the Mayo Clinic (Walters, Gray, and Priestley, 1940) between the years 1907 and 1938 out of 11,000 carcinomas of the stomach there were 2,840 resections, of which only 27 were total.

According to Kronlein (quoted from Finney and Rienhoff, 1929), total gastrectomy is defined as removal of the whole stomach so that in the specimen is found a portion of oesophagus at one end and of duodenum at the other. Billroth (quoted from Finney and Rienhoff, 1929) defined as a total gastrectomy resection of the body followed by anastomosis of the pylorus to the cardia—these we prefer to term subtotal gastrectomy. Finney and Rienhoff in 1929 traced 110 of the reported cases, of which only 67 were in the first group; it is solely with this latter category of complete (total) gastrectomies that we shall deal.

History

Phineas Conner (1884) of Cincinnati performed the first total gastrectomy on a moribund patient, who did not survive the operation. Carl Schlatter (quoted from Finney and Rienhoff, 1929) in 1897 recorded the first successful case, which survived the operation 14 months. In 1898 MacDonald and Brigham each recorded successful cases, and, following these, reports of sporadic cases continued to appear, chiefly in America and on the Continent.

The first annotation in this country is by Chavasse (1899), who was unable to follow the gastrectomy by an anastomosis and, having closed the oesophagus, brought the duodenum out on to the skin surface, the patient dying soon after. In 1903 Moynihan published the first full report of a case in this country, the patient dying from shock 36 hours after operation. His second case (Moynihan, 1907), operated upon for linitis plastica in 1907, developed a profound anaemia three years later, but survived for a further period of 8 months. Necropsy showed no evidence of recurrence. In 1928 Flint of Leeds reported a successful case operated upon for diffuse encephaloid carcinoma. This patient, aged 44, was alive and well 18 months later. According to Rodney Maingot (1941), Walton had reported 6 cases, Gordon-Taylor 6, Maingot 6, and Joll 12,* but these appear not to have been fully recorded, which seems to us to justify publication of the present review.

In 1929 Finney and Rienhoff collected 67 cases of total gastrectomy, and in 1933 Roeder added another 21, making altogether 88 cases. Since those two excellent papers, with very complete bibliographies, a number of cases have been reported upon, but chiefly as examples of successful technique, and they were often recorded within a month of the actual operation:

Author	*Remarks*
Clute and Mason (1930) ..	Survived 3 years 6 months
Morrison (1933)	Aged 53. Alive and well after 6 months
Atkinson and Masson (1934) ..	Aged 62. Successful case
Percy (1934)	Aged 59. Survived 19 months
"	Aged 64. Survived 5 months
Streicher (1934)	Aged 45. Alive and well 10 months later
Jennings (1936)	Aged 35. Successful case
Walton (1936)	6 total gastrectomies out of 173 resections in 461 cases of carcinoma ventriculi
Clute and Albright (1937) ..	Quote Bull and Stang's case: 13 months
" " " (1937) ..	Quote Clute and Mason's case, above
Walters and Horton (1937) ..	Aged 61. Alive and well 6 months later
Allen (1938)	16 cases. One alive and well after 4½ years. 8 survivals
Lahey (1938)	9 cases—5 survivals. One, aged 36, worked 3 years and lived 3 years 4 months
Neel and Waugh (1939) ..	Aged 43. Alive and well after 8 months
" " " ..	Aged 68. Alive and well after 6 weeks
" " (1940) ..	Aged 45. Alive and well after 5 months
Lemmon and Paschal (1940) ..	Aged 63. Alive and well after 7 months
Graham (1940)	19 cases—5 survivals: one alive and well after 19 months
Priestley and Randall (1941) ..	Aged 31. Alive and well after 8 months
Donald (1941)	Aged 44. Successful case
Waugh and Giffin (1941) ..	Aged 72. Successful total gastrectomy and partial oesophagectomy
Jackson (1941)	Aged 69. Alive and well after 26 months
Jordan (1941)	Total gastrectomy for leiomyosarcoma. Alive and well after 2 years 9 months
Morrison (1941)	2 cases. One alive and well after 26 months
Lynch and Priestley (1941) ..	Aged 55. Alive and well after 3 months
Baker (1941)	Aged 60. Successful case
Jones (1941)	Aged 44. Fit for 16 months

Technique

Most authors stress the value of spinal or local anaesthesia followed by gas-and-oxygen, and ascribe the technical difficulty of the operation not to the oesophago-jejunal anastomosis but rather in mobilizing the stomach, fixed as it may be by perigastric adhesions or neoplastic infiltration. Stress is laid on the principle, first introduced by Moynihan (1907), of utilizing the stomach as a retractor. An interrupted anchor layer of sutures and a second continuous layer of sero-muscular sutures having been inserted, small openings are made into the left extremities of oesophagus and jejunum, and only when these small openings have been approximated by a through-and-through layer are the incisions extended. Certain surgeons advocate oesophago-duodenostomy, but most prefer an end-to-side oesophago-jejunostomy. An entero-anastomosis is added by some, while Finney and Rienhoff (1929) advocate using the Levine duodenal tube. This is swallowed before operation and manipulated through the new stoma into the jejunum at the operation in the hope of minimizing the risk of early leakage from the suture line. If a short oesophagus is exposed it may be necessary to cut the left triangular ligament of the liver to allow of a more adequate exposure. Lahey (1938) and others advocate the use of flaps of diaphragmatic peritoneum to cover the anastomosis. Priestley and Randall (1941) suggest anchoring the jejunum posteriorly to the pancreas and anteriorly to the liver to prevent traction, and use jejunal feeding to prevent leakage.

As some of the recorded cases show, provided the patient's general condition is good, age is no barrier to the operation. Thus Jackson (1941) reports the case of a patient aged 69 who was alive and well 26 months after total gastrectomy for linitis plastica. Waugh and Giffin (1941) had a success in a man aged 72—the oldest recorded case. To justify the operation the lesion should, however, be confined to the stomach, together with, at most, the immediate regional lymph glands; and the oesophagus should be mobile enough for anastomosis (Neel and Waugh, 1939). If possible, 4 cm. proximal to the growth should be removed for fear of intramural extension, according to Adrian Verbrugghen (1931), but this must be considered a counsel of perfection.

Complications and Prognosis

Finney and Rienhoff (1929) give the immediate mortality of the 67 cases recorded as 53.8%, of which peritonitis accounted for 58% and shock 8%, the remaining deaths being due to intestinal obstruction, enteritis, duodenal fistula, oesophageal fistula, haemorrhage, cardiac failure, or cerebral haemorrhage. They point out that oesophago-duodenostomy was followed by a 67% mortality due to peritonitis, in comparison with 50% of those on whom oesophago-jejunostomy was performed. According to Roeder (1933) the first 88 recorded total gastrectomies had an immediate post-operative mortality of 50%, due chiefly to shock, peritoneal or pulmonary infections, and haemorrhage.

The most common immediate post-operative cause of death is not leakage from faulty suture but rather the extent and duration of the operation in a gravely debilitated patient. Whether post-operative shock and pulmonary infections can be reduced, by adequate pre-operative treatment directed towards increasing the patient's resistance combined with blood transfusions and prophylactic oral and local sulphonamides, is still uncertain. The figures from the Mayo Clinic (Lynch and Priestley, 1941) are, however, encouraging: during 1907-38 there were only 9 survivals out of 27 total gastrectomies, whereas in 1940 there was only 1 death out of 8 cases.

---

* This figure now stands at 22.

Post-operative vomiting is rare in the uncomplicated case. Some develop a mild glossitis and stomatitis, though diarrhoea seldom occurs. The development of a moderate degree of secondary anaemia is fairly common. In Moynihan's successful case death occurred 3 years 8 months after operation—not from recurrence but from anaemia.

The development of megalocytic anaemia is questionable. Chester Jones (1940), in a very excellent review of the problem of gastrectomy and the anaemias, says: "It is apparent that major gastric surgery—subtotal or total—may be performed without any great fear of undue consequences as far as the factor of normal haematopoiesis is concerned. Despite the fact that relative or absolute achlorhydria develops, and secretory cells of importance to normal blood physiology are removed, the development of serious anaemias is not to be feared. An occasional microcytic or macrocytic anaemia ensues in the course of months." He concludes that extragastric lesions must coexist for the production of Addisonian anaemia—possibly due to the destruction of argentaffin cells in the duodenum, small intestine, colon, and appendix, those in the stomach having been already removed—and that an adequate and well-balanced diet should suffice to prevent its occurrence.

Karl Meyer (1941) suggests that pernicious anaemia does not occur after total gastrectomy only because the patients do not often survive long enough. He reports a case of total gastrectomy performed in Oct., 1933, for chronic non-specific linitis plastica in which the pre-operative haemoglobin was 80% and erythrocytes 4,220,000. In 1938 the latter were 5,000,000; but in 1939—6 years after operation—the patient developed the typical haematological picture of pernicious anaemia.

Rowlands and Levy Simpson (1932) collected 17 cases of Addisonian anaemia following gastric operations, of which 5 occurred after total, 8 after partial gastrectomy, and 4 after gastro-enterostomy: considering the rarity of total gastrectomy this is a high incidence.

Prognosis

From the standpoint of the restoration of health the results of the operation are, however, distinctly favourable. The patients have good appetites and enjoy life; many return to work and can lead a normal existence. Roeder (1933), moreover, makes the interesting observation that in his surviving case the patient experienced normal sensations of hunger despite the absence of the stomach, which has hitherto been considered as the exclusive somatic site for hunger.

The immediate post-operative mortality is, however, high (53.8% according to Finney and Rienhoff, 50% according to Roeder), though among 8 cases of total gastrectomy performed at the Mayo Clinic during 1940 (Gray, Walters, and Priestley, 1941) there was only one death—a mortality of 12½%. The ultimate prognosis as regards survival after operation is disappointing, the average duration of life being well under two years—almost all dying of metastases. The survival period of 20 cases from the Mayo Clinic (Eusterman and Balfour, 1935) is as follows: One case lived 3 years 9 months; two cases lived 2 years 8 months; one case lived 2 years 3 months; 16 cases lived for less than a year after operation.

The following are the longest recorded periods of survival from a careful study of the literature available in the English language:

(1)	Moynihan	3 years 8 months. Died of secondary anaemia
(2)	Zikoff	4 years 8 months
(3)	Mayo, W. J.	2 years 11 months (3 years 9 months). Died from ? pernicious type of anaemia
(4)	Brun	4 years
	(The above four are quoted from Finney and Rienhoff, 1929.)	
(5)	Allen (1938)	4 years 6 months. Alive and well at time of report
(6)	Lahey (1938)	3 years 4 months. Died of recurrence
(7)	Jordan (1941)	2 years 9 months. Total gastrectomy for leiomyosarcoma. Alive and well

Two Personal Cases

To the above list we wish to add the following 2 cases—the first surviving for 3 years 2 months and the second for 3 years 6 months after total gastrectomy.

Case E. A.

The first patient, a man aged 45, presented himself at the Royal Free Hospital on Dec. 9, 1932, with a history of vague indigestion of some years' duration. Following a haematemesis in April of that year he had complained of attacks of abdominal pain half an hour after food, relieved by vomiting. Despite melaena he felt fit, his appetite remained unimpaired, and there had been no loss of weight.

Clinical examination showed a thin but otherwise healthy individual. A blood count showed R.B.C. 3,030,000; Hb 49%; C.I. 0.81; W.B.C. 11,500. Operation on Dec. 12, 1932, disclosed on the posterior wall of the stomach a large ulcer with a raised red indurated edge extending up to the cardiac orifice. A total gastrectomy with retrocolic oesophago-jejunostomy was performed, and after an uneventful convalescence the patient was discharged a month later. He resumed work immediately for economic reasons. Section revealed an "ulcer-cancer." The glands showed chronic inflammatory changes and the effects of lymphatic obstruction only.

Two years later, in Jan., 1935, he was readmitted with pain in the left hypochondrium which had been present for 6 months and was aggravated by food. In addition he occasionally vomited yellowish watery fluid and this was associated with black stools. A blood count showed a marked hypochromic normocytic anaemia with R.B.C. 3,790,000, Hb 39%, C.I. 0.5, and W.B.C. 14,500, and the stools contained occult blood. Barium passed normally down the oesophagus and there was no demonstrable abnormality of either the afferent or efferent loop or at the anastomosis.

In Oct., 1935—34 months after operation—he was readmitted on account of burning pain in the epigastrium and difficulty in keeping solid food down. Clinical examination revealed no evidence of recurrence; barium, however, was held up at the lower end of the oesophagus, which was constantly craggy, and was convulsively regurgitated into the upper part. There was no sign of any fistula into the colon. He returned home a month later to a lighter form of work and died on Feb. 12, 1936—3 years 2 months after his operation.

Case J. K.

The second patient, a woman aged 42, was admitted into the medical wards on July 25, 1938, complaining of epigastric discomfort and pain of two months' duration. This pain appeared 2 to 3 hours after food and was relieved by alkaline powders and by light diet. Her initial nausea had been followed by attacks of retching, during which she vomited small amounts of watery fluid which was occasionally blood-stained. Her bowels had been costive, and on two occasions her stools had been dark and tarry. Her appetite was poor and she had lost 12 lb. in the preceding two months. She stated that she had had indigestion for years, and two months previously had undergone an operation for acute appendicitis.

Clinical examination showed a pale emaciated patient. There was visible epigastric peristalsis and a hard irregular mobile ovoid mass in the epigastrium. Investigations were as follows:

June 16, 1938.—Barium meal. Immediate: Projection on posterior surface in middle third. Peristalsis quiet. Pylorus relaxes at once. Duodenal cap normal. (Fig. 3.)

July 20.—Barium meal. Immediate: Irregular projection on greater curvature coincides with the mass palpable half an hour after the meal. Appearance strongly in favour of rapidly advancing neoplasm. (Both meals before admission.)

July 25.—Blood count: Hb 68%, R.B.C. 4,340,000, C.I. 0.79; W.B.C. 7,750 (polymorphs 74%, lymphocytes 21%, monocytes 4.5%, basophils 0.5%). Red cells show anisocytosis, hypochromasia, and polychromasia.

July 26.—Stool: Test for occult blood positive.

July 27.—Histamine test meal: Volume of resting juice 25 c.cm. Some red blood cells and debris; pus cells. Raised normal curve.

Aug. 8.—Hb 70%, R.B.C. 4,860,000.

Operation.—Pre-operative medical treatment was given. Operation was performed on Aug. 8 by one of us (C. A. J.), cyclopropane anaesthesia being administered by Dr. Morris. The findings were: carcinomatous leather-bottle stomach extending to within an inch of oesophageal opening and to within 1 in. of the pylorus; enlargement of glands along the greater curvature; no evidence of metastases. The procedure was as follows. The pylorus and first part of the duodenum were mobilized; the latter was divided between crushing clamps and the distal end closed. The greater omentum was completely dissected from the colon. The lesser omentum was divided, and stomach and as much of the intrathoracic oesophagus as possible were mobilized. Through the transverse mesocolon a loop of jejunum was brought up to the oesophagus and, following Moynihan's technique, an oesophago-jejunostomy was performed. Failing to cover the suture line with omentum, the abdomen was closed.

The operation took 1 hour 10 minutes; the patient returned to the ward in good condition. She was given rectal salines 4-hourly, and on the next day was taking 1 oz. of water hourly by mouth. This was gradually increased, and by the third day she was having small amounts of milk. Subsequently a diet of high caloric value was added, so that within a week she was taking a fair quantity of food at 2-hourly intervals. A fortnight later the patient was up and about, taking 2-hourly feeds of chicken, potatoes, eggs, fish, etc. She was allowed home 22 days after operation.

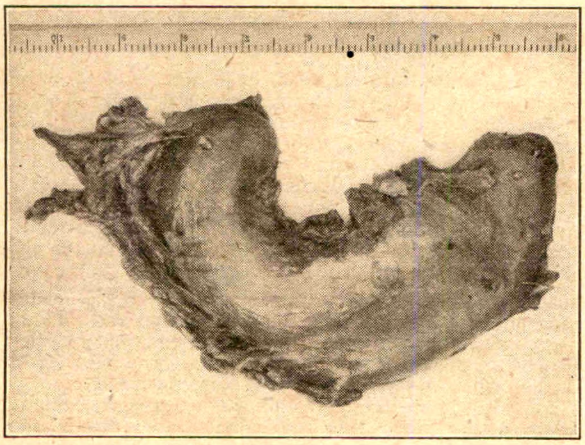

FIG. 1.—Case J. K. Stomach and great omentum after removal, showing widespread carcinomatous infiltration from cardia to pylorus.

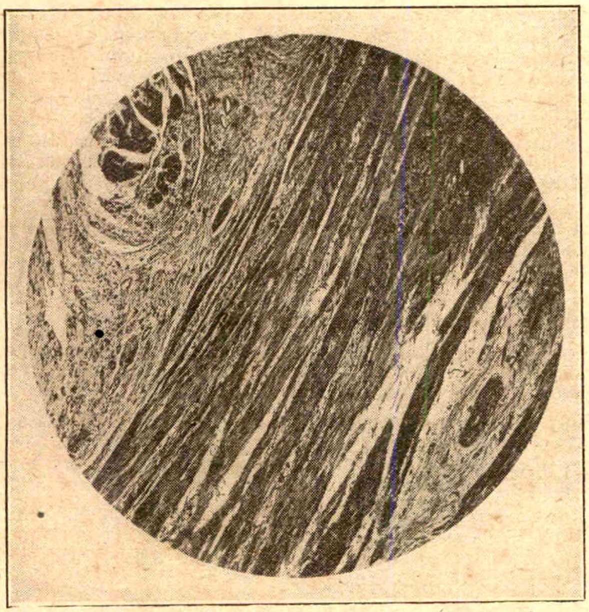

FIG. 2.—Case J. K. Photomicrograph from section of gastric wall to show muscular hypertrophy and focus of adenocarcinoma.

Pathological Report.—" A ' leather-bottle ' or diffuse type of carcinoma of the stomach extending from the oesophagus to the pylorus and involving the whole of the lesser curvature and portion of the greater curvature. The wall of the stomach is considerably thickened and all the coats are invaded by tumour cells in the region of the lesser curvature, producing ulceration of the surface mucosa; elsewhere the normal mucosa is intact. Microscopically, the malignant cells are irregularly scattered through the stomach wall and associated with a generalized fibrosis. An occasional irregular acinus is formed, and some of the cells contain mucous globules. Lymph glands along both curvatures are not enlarged, but several contain microscopic growth." (Figs. 1 and 2.)

Subsequent Progress.—The patient a year later was enjoying life and her food—four square meals a day. In March, 1941, one of us (C. A. J.) removed bilateral Krukenberg tumours, section of which showed adenocarcinoma with low mucus-secreting columnar cells suggesting secondary carcinoma from stomach. She was readmitted for investigation on Oct. 19, 1941, 3 years 2 months after her gastrectomy, during which period she had been doing all her housework, including the

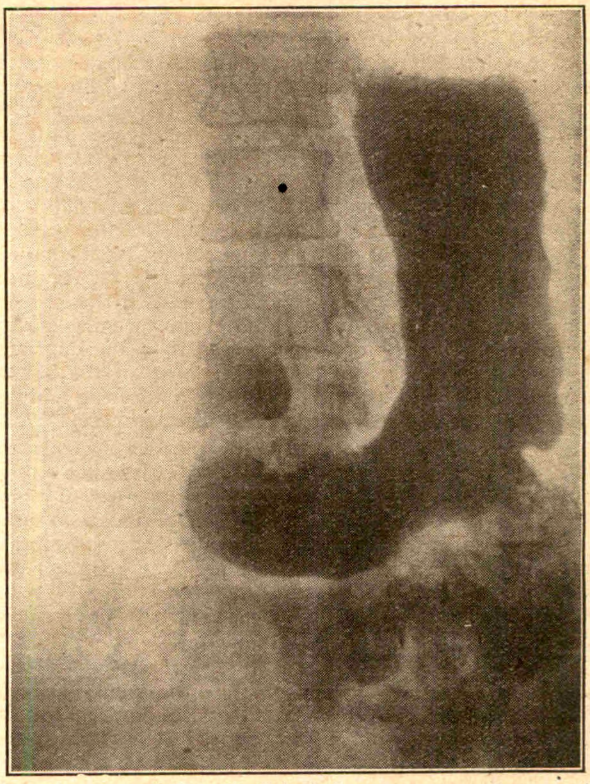

FIG. 3.—Case J. K. Radiological appearance of stomach immediately after barium meal (erect).

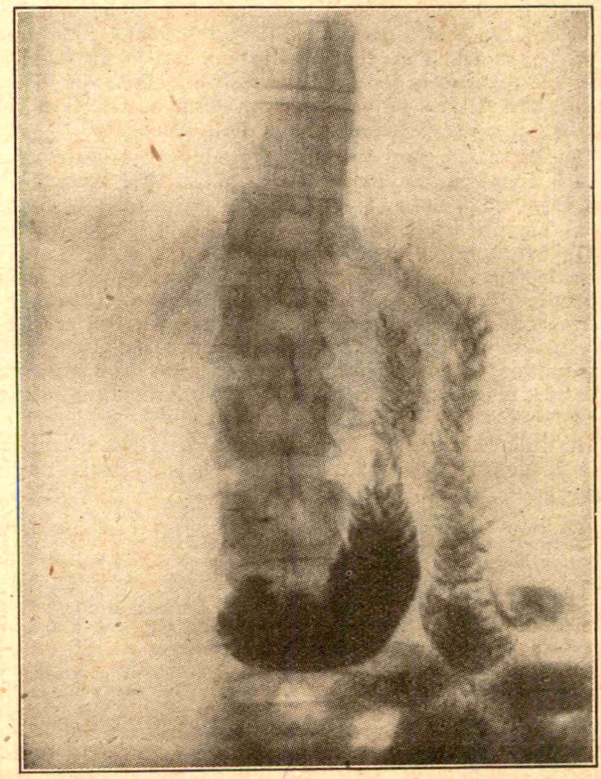

FIG. 4.—Case J. K. Post-operative radiograph showing barium passing direct from oesophagus to jejunum.

laundry and looking after her two children. A blood count showed Hb 58%, R.B.C. 2,960,000, C.I. 0.98, W.B.C. 11,400. The red cells were normal in size, shape, and staining. The white cells were of normal adult type. A radiograph of the chest revealed no abnormality. A barium meal showed total gastrectomy, with a filling defect in the transverse colon. (Fig. 4.)

She was discharged home a few days later and died on Feb. 5, 1942—3 years 6 months after total gastrectomy. No necropsy was performed, though she must certainly have died of abdominal metastases.

Summary

A brief review of total gastrectomy shows that the operation is indicated for patients in good condition when the carcinoma is operable and the anastomosis can be performed without tension.

Life after total gastrectomy is on the whole short, though those that survive may enjoy reasonably good health without any serious dietetic restriction.

A further 47 successful cases have been collected from the available English literature since Roeder's article in 1933, making a total of 135 reported cases of total gastrectomy.

In addition two personal cases surviving the operation by 3 years 2 months and 3 years 6 months, respectively, are described.

The annual general meeting of the British Social Hygiene Council, the first since it became an independent voluntary body with no financial or other control by the Ministry of Health, was held at B.M.A. House with the president, Sir Walter Langdon-Brown, in the chair. The council is now devoting its energies to the promotion of social biology, including the social implications of venereal disease, and the president took as the subject of his address "The Place of Social Biology in the Sciences." He stressed the interdependence of all life, pointing out that all living organisms, from the lowest to the highest, were governed by the same natural "laws." After showing that the kinetic energy of animals was derived from the potential energy stored in plants, he traced the progressive stages in animals from reflex action to instinct, from instinct to intelligence, and from this to the still higher values of life. The annual report of the council was adopted, and on the motion of Mr. McAdam Eccles the officers were re-elected, as also was the executive committee, which was strengthened in the field of social biology by the addition (*ex officio*) of the chairmen of the newly appointed committees, including Prof. F. A. E. Crew, F.R.S., and Sir Francis Fremantle.

PREPARATION OF THE HANDS FOR OPERATION

BY

W. A. COCHRANE, F.R.C.S.Ed.

Surgeon, Princess Margaret Rose Hospital, Edinburgh; Associate Assistant Surgeon in Orthopaedics, Royal Infirmary, Edinburgh; Lecturer in Orthopaedic Surgery, University of Edinburgh

If the shortage of gloves continues we may, as a war necessity, have to operate without them. In point of fact, the use of rubber gloves in surgery is comparatively recent: they were introduced in the early years of this century. I have it on the good authority of a surgeon who operated before that time that the cases did well. I operated without gloves for some years as assistant to Sir Harold Stiles, who did not use them in clean cases. I have no recollection of a single case becoming infected. The following method, which I was taught to use and which I habitually employed, may prove of interest and value to surgeons and nurses. It is reliable. It takes a little time and trouble, but safe hands are worth it. As one becomes expert the time taken can be shortened.

The Procedure

Three washings are carried out. The first is for 10 minutes in a sterile basin half full of very warm water, to which soap spirit has been added. It is whipped up into a good lather. A soft but firm sterile nail-brush is used to scrub the fingers and palms, particularly in the line of the skin folds—i.e., across the hand. The scrubbing should not be strenuous on the backs of the hands, the wrists, forearms, and elbows, as the skin in these situations is thin. Special attention is paid to the tips, sides, and clefts of each finger, with the hands in the lather. A test of one's efficiency is to cover the hands with lamp-black in oil and wash them off in the dark or blindfold. Any parts still black will show what areas are being inadequately scrubbed.

For the second washing, the basin is filled with a change of warm water. Soap spirit is added as before, and a tablespoonful of cresol. The process of washing and scrubbing is repeated for 5 minutes.

A final wash of 3 minutes in a fresh sterile basin, with another sterile brush, rather softer than the other, and using water and cresol only, is given. The hands, wrists, and forearms are then rinsed in warm sterile saline.

During the operation the surgeon uses two lotion-basins: one contains warm sterile water and cresol, the other sterile saline. The former is for washing blood from his hands, which are then passed through the saline. Cresol and water are ideal for clearing the hands of blood. Somebody may say that cresol, lysol, or antiseptol used in the manner indicated will irritate the skin. If one obtains a good antiseptic of this type, this is not likely to happen, especially if on completing the operation a point is made of washing the hands and arms with soap under the running tap. This is an important point to remember.

An operation begins with the preparation of the hands. Whichever plan is adopted, it should be thorough and unhurried, whether gloves are used or not. It must stand up to the test of producing good results. For those who have never tried to operate without gloves I can give the assurance that there need be no alarm on that score if the above method is carefully employed. I think that an antiseptic is required. It is for this reason that I prefer use of the sterile basins rather than washing-up beneath the running tap with soap and water only.

The best way to scrub the finger-tips and the backs of the fingers is by holding the brush steady beneath the lather, bristles uppermost, and moving the fingers of the other hand rapidly to and fro across it. Between operations, the final washing described above is repeated for about 2 minutes. If a very pure cresol is used it can be in surprising concentration actually without irritating the skin: the surgeon soon learns by experience how much to use. In the first wash-up the soap spirit is poured in from a bottle; the soap spirit and the cresol in sterile dishes are placed at the surgeon's side.

Medical Memoranda

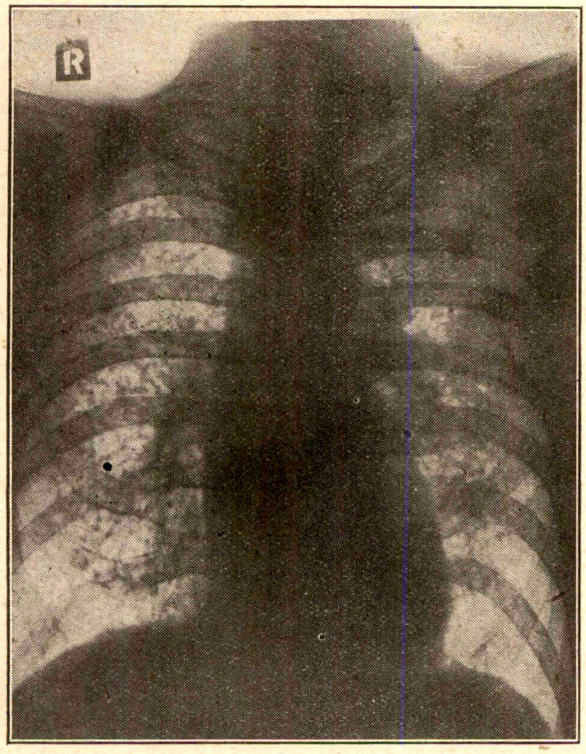
Silicosis in a Chert-miner

The following case seems to be worthy of record in that it is, so far as I am aware, the first case of silicosis occurring in a chert-miner to be definitely acknowledged by the Silicosis Board, and in fact the only undisputed case of silicosis due to chert yet reported—a recent case having proved negative on post-mortem findings although compensation was paid during life.

Chert, or petrosilex as it was formerly called, is a very hard rock or flint stone. It can be of various colours—blue, black, or white. In some cases chert is solid all the way through; in others it is in layers with the limestone, and is called roof chert. It is a compound of silica and limestone, and 80% is mined in Bakewell, Derbyshire. The proportion of silica varies in different specimens, being within the wide ranges of 30% and 90%. Chert is used for grinding all pottery materials, and in glazing; it is ground into paste in the Potteries. Before this war it was constantly being exported.

Case History

I first sent this man in Jan., 1934, to see Dr. P. Heffernan, who was unable to find any signs of tuberculosis in his chest. Although periodical radiographs have been taken regularly and the sputum has been examined for the tubercle bacillus the results have always been negative. The first, taken in 1934, showed a most perfect picture of silicosis—just like a snowstorm; and plates have been taken at regular intervals for the past 9 years. The radiograph here reproduced was kindly taken for me by Dr. Grout of Sheffield in 1939. (It is only owing to absence on war service that I have not published the case before.) It shows nodular fibrosis in each lung. The chief symptoms in this case were shortness of breath, cough with some sputum, and a feeling of weakness and tiredness. The man's history is particularly important in view of the hand labour, subsequently replaced by machine labour.



Radiograph of the case, showing nodular fibrosis in each lung.

The patient was born in 1886 and started work in 1898 at mine A, working below ground as a drill-turner with the striker beside him. The men worked unprotected, and dust flew about. In 1899 hand work was done away with and machinery was introduced in the limestone. Subsequently he was a poker-holder on the boring machines for 2 years; then a machine driver for 4 years. He subsequently worked for about 14 years in the chert—all hand striking and hand boring. He left Mine A and went to Mine B, where he worked for 11 years in the chert—all underground work, all machine boring. In all, he worked about 31 years in chert. He left work in 1935. Full compensation has been agreed to, and paid since 1936. One fact should be mentioned in all fairness. In 1918 he left chert for 3 weeks and was employed in sandstone, but he was only cleaning up, and did not actually work in sandstone himself, so I feel that this period of 3 weeks can be overlooked. At one time he drank a fair amount of alcohol after work, and the fact that he did so may have been a contributory cause of his sensitivity to absorption of silica dust. He also had some degree of cirrhosis of the liver and has had more than one attack of delirium tremens. The radiograph in this case is diagnostic and conclusive.

My thanks are due to Dr. P. Heffernan for his great help in the diagnosis of this case.

Bakewell. Late Capt., R.A.M.C.

Acute Benign Dermatomyositis

A mild type of myositis or myalgia has been described from time to time under the heading of Bornholm disease. The pain is upper abdominal or thoracic, of abrupt onset and severe, and accompanied by fever and sweating. It has been regarded as a toxic myositis due to a specific infection, since on occasion it appears as a small epidemic. Hypersensitivity of the skin does not form part of this syndrome, but a combination of myositis with tender skin and peripheral neuritis has been recognized and described under the term dermatoneuromyositis. Such cases are usually grave, since a residual fibrosis of muscle and skin leads to the condition of sclerodermia, which has only recently been recognized as the sequela of an acute dermatomyositis. Intermediate forms are probably not uncommon. Williams (1941) described 5 cases of benign dermatoneuromyositis occurring shortly after inoculation with typhoid vaccine. There were meningeal symptoms, and the spinal fluid showed an increase of cells but was sterile. He gave reasons for considering allergy not the essential cause, and attributed the illness to a virus infection. The isolated case described below would seem to be another variant of the same syndrome.

Case Report

A farmer aged 32 was admitted to the Royal Northern Infirmary on April 21, 1942, as an emergency case. On April 11 he had felt tired and rather stiff after working late mixing pig food. This slight stiffness and tiredness persisted for the next 3 days, when he had a bout of sneezing, and on the following day, April 16, he had frontal headache and a general increase in the feeling of stiffness. Seen by his doctor on the 18th, he had a temperature of 101° F. and a pulse of 68, and on this day developed retention of urine and vomited repeatedly. He described severe headache, both frontal and occipital, and epigastric pain. He now began to find his skin very tender, and noticed that any little effort made him sweat profusely. He was catheterized twice by his doctor before admission to hospital.

He was afebrile after reaching hospital. Any movement, except of the hands, gave him acute agony. He preferred to remain in a half-sitting position, and could not bear to feel the bedclothes touch his skin; but over certain parts—e.g., in the left leg and the right thigh—there were areas of reduced sensibility to superficial stimuli. No reduction in appreciation of temperature was present, but cold objects were felt as painful. Sense of position and localization and vibration were all intact. Over the trunk and the greater part of the limbs light touch felt to him as if he were being rubbed with sandpaper. Photophobia was present. He was catheterized without any difficulty, and retention appeared to be due to the extreme pain occasioned by efforts at voluntary micturition. No physical signs apart from those described were found in the nervous system or any other system. His spinal fluid on April 23 was completely normal, and the white cell count on the same day was 5,200 per c.mm. (polymorphs 49%, lymphocytes 46%, monocytes 4%, eosinophils 1%). Within 3 days of admission he was able to move about quite freely and there was no further retention of urine. At the end of a week all his symptoms had disappeared except for a feeling of numbness and altered sensation to light touch in the legs. He was discharged from hospital after a fortnight and was seen again a month later; he was then in perfect health except that he still complained of a slight sensation of numbness in his feet.

Reviews

MACHINERY OF A MEDICAL ORGANIZATION

The Political Life of the American Medical Association. By Oliver Garceau. (Pp. 186. 14s.) Massachusetts: Harvard University Press; London: Oxford University Press. 1942.

This is a sociological study of the machinery of a medical organization by a lay expert whose basic interest is in the influence on the State of the "group," which he describes as representing a point of view "which cannot be expressed in ordinary politics by the individual voter." Groups are "not only wholesalers but manufacturers of opinion." The community judges a group largely by the way in which it conducts its affairs. Mr. Garceau chose the A.M.A. for his study because of its size and importance and because it is a professional group. A profession he describes as a group whose code of ethics is potentially powerful enough to "raise individual conduct above the level it would otherwise attain." By the light of this high standard he examines the political record of the A.M.A. in what appears to be a scientifically objective way.

He finds it defective in its power or its willingness to provide for the effective outlet of minority opinion. As an example, he accuses it of deliberate suppression in its journal of information on the burning question of State insurance coming from authoritative quarters in countries where the experiment has been made. Examining its ethical machinery, he is of opinion that co-called medical ethical questions are mostly matters of economics. He thinks that the machinery of the A.M.A. has "borrowed from its surroundings the powerful myths of oligarchy, a little tyranny, an elaborate democracy, and a strain of aristocracy." He sharply criticizes the absence of real control by the House of Delegates (the opposite number of our Representative Body) over its administrative officers and its budget.

He makes full allowance for the difficulties of organization over such a wide area, comprising 48 States with differing legislations, but he thinks that the leadership of the Association is very astute and has little to learn from the professional politicians at Washington. In spite of its great efforts at centralization he thinks it is on the whole still rather a federation than a centralized national organization. He observes signs that an influential minority movement may be developing, headed by "the Committee of Physicians," a small central body containing many influential men whose avowed object is to act as "the nucleus of liberal and progressive thought inside the A.M.A." He makes some interesting remarks on the familiar point that the average medical man has no use for medical politics. Indeed, he offers the plausible excuse for him that, contrary to the average citizen, he can find in the practice of his profession all the mental stimulation he requires, whereas the general body of citizens need some form of "extra-mural" activity, of which politics is one of the most obvious. He is strongly of opinion, however, that in neglecting the politics of his group the indifferent doctor is wrong. Skill in politics, he says, is as necessary to successful social life as the development of surgical skill or the control of disease. Holding this deal of politics he pleads that what the medical profession needs is more medical politicians of the right kind and not fewer. To the criticism that laymen are not fit to have an opinion on medical matters, he opposes his view that that does not apply to the politics and economics of the profession, which are of the same order in all spheres of life. He ends by saying: "It would be a tragedy for the whole community if the A.M.A. fails to elicit public respect. The answer lies in the political ife within the A.M.A. itself."

The book is of great interest to all who believe that the medical profession is destined to play an increasing part in national affairs; and though the problems of the American profession differ in many ways from those of other countries, hey are the same in essence. This study can be cordially ecommended to all who believe it to be a duty to see that a medical organization should exist, not only for the support and protection of its members, but in order to bring the egitimate and special influence of the profession to bear on he affairs of their country.

A. C.

CANCER OF THE UTERUS

Cancer of the Uterus. By Elizabeth Hurdon, C.B.E., M.D. Oxford Medical Publications. (Pp. 188. 17s. 6d.) London: Oxford University Press. 1942.

The incidence and mortality of carcinoma of the cervix present to obstetricians and gynaecologists the greatest problem they have yet had to solve. The great work of Wertheim in Vienna and Bonney in this country resulted in the development of a superb technique for the radical abdominal treatment of operable cases. Meanwhile Schauta was perfecting the radical vaginal operation which now has many supporters in Continental clinics. The best results obtained by either technique were encouraging rather than satisfying. With the advent of modern methods of intracavity radiation supplemented by external radiation new methods of treatment were developed, and with them came new hope for the future. The time is opportune for a wide survey of the problems involved, and for this reason an enthusiastic reception is assured for *Cancer of the Uterus* by Dr. Elizabeth Hurdon. The book is a masterly production written by one who had a wide and intimate knowledge of her subject. She had worked as an associate in gynaecology at Johns Hopkins University, where with Dr. Howard Kelly she first studied the pathology of uterine cancer and the modern methods of radiation treatment. Later Dr. Hurdon was largely responsible for establishing a unit for the radium treatment of cancer in women at the Marie Curie Hospital, London, where she held the post of medical director until 1938. Following her resignation Dr. Hurdon devoted the last years of her life to writing this book. She did not live to see its publication, but in its pages she has made a contribution to the common cause possibly even greater than that which was made by the outstanding work of her lifetime. The book gives a comprehensive and statesmanlike review of the whole subject and points the way to future progress.

The claim is made that with early diagnosis and adequate treatment 60 to 70% of cases of cervical carcinoma and 80 to 90% of cases of carcinoma of the corpus might be cured. That these figures are not idle ones is shown by the fact that in the results published from the Marie Curie Clinic the absolute 5-year survival rate in Stage 1 and Stage 2 cases was 80% and 61.5%, and the 10-year absolute survival rate was 63.6% and 41.9%.

The book opens with a general survey of the carcinoma problem in which such subjects as the incidence, nature, and ultimate cause and predisposing factors are discussed. An excellent account of the clinical pathology in all its aspects is then given. One minor criticism concerns the reference to superficial curettage as a means of obtaining biopsy material, for no warning is given of the very real danger of missing an underlying infiltrating growth. The treatment of cervical cancer is then discussed in great detail and the position as it now stands is reviewed impartially and clearly. An excellent chapter is devoted to the treatment of the operative complications, such as tumour infection, pyometria, anaemia, and pelvic sepsis. The post-operative complications are discussed with equal thoroughness and clarity. The important problem of carcinoma of the cervical stump following subtotal hysterectomy receives the attention it merits. There were 27 of these cases in a total of 1,296 cases reviewed, with an additional 7 cases in which the cervix was the seat of carcinoma at the time the subtotal hysterectomy was performed. One chapter is devoted to the subject of carcinoma of cervix and pregnancy, and includes a most interesting review of the literature, in which are recorded 15 cases of pregnancy following irradiation for carcinoma of the cervix. Carcinoma of the corpus, vagina, and vulva, and sarcoma of the uterus are all separately considered. Endometriosis is discussed, but not very fully, and the chapter on this could well be omitted from subsequent editions or else revised to give a broader survey of the problem of treatment of this not uncommon condition. A final section deals with radiation therapy for uterine haemorrhage in non-malignant disease.

The book has been very carefully produced, is well illustrated, and should have a place of honour near the desk of every gynaecologist. If every general practitioner also had a copy and gave heed to its teaching the day of 60 to 90% cures for carcinoma of the uterus might dawn sooner than we at present dare hope.

MEDICAL JURISPRUDENCE

Medical Jurisprudence and Toxicology. By John Glaister, M.D., D.Sc. Seventh edition. (Pp. 671; illustrated. 28s.) Edinburgh: E. and S. Livingstone.

Since its first appearance in 1902 Glaister's *Medical Jurisprudence* has gathered very many devoted readers, for whom it is the trusted arbiter in every medico-legal doubt. They will welcome the appearance of the seventh edition. Among the improvements which Prof. Glaister has made are the elimination of small type, and the collection of bibliographical references at the end of each section. He has completely recast the book and almost entirely rewritten it. He has brought up to date his references to legislation and has included notes of many recent legal decisions, and most of the medical cases cited for illustration are new. The section on toxicology, the subject with which the author's reputation is more particularly associated, has been drastically revised, and he has included descriptions of additional poisons. He has wisely excluded most of the earlier accounts of methods of quantitative estimation, judging that such matters are for the analyst and are outside the scope of the medical practitioner. He, however, gives adequate reference to authoritative works on the interpretation of the results of analysis, and describes qualitative tests. He has omitted emergency legislation—very little of which, in any event, bears on medical jurisprudence—except for an appendix on the procedure when death follows an air raid and is therefore outside the duty of the coroner. His last chapter deals with war gases and the effects of blast, but not with the interesting effects on the kidney of crush injuries, which has attracted so much attention during the last two years. His account of the law of forensic medicine is very condensed but adequate for most everyday purposes of the practitioner, and includes the law both of England and of Scotland. The photographs are as good as ever, and the paper shortage has made no difference to the excellence of the presentation.

Notes on Books

War Gases and Foodstuffs, by W. R. Wooldridge, Ph.D., M.Sc., contains a discussion of the properties of war gases and of their effects on various kinds of food, and is directed chiefly to the consideration of the possibility of salvage of contaminated foods. The subject is treated from manifold aspects, regard being paid to the many different problems arising from different conditions and circumstances. The book provides useful reading, but may appear more academical than helpful to the reader seeking practical guidance. It is published in London by Leonard Hill Ltd., of 17, Stratford Place, W., price 2s. 8d. post free.

Preparations and Appliances

THE "RAILED" SPLINT

Drs. G. A. Pollock and George Brooks, of the Wilkie Surgical Research Laboratory, University of Edinburgh, write:

The rate and extent of recovery of joint function after operative procedures on the articular structures or injuries to the related bones depend largely on the patient's ability and willingness to co-operate in his post-operative care. In our experience pain is one of the most important factors in delaying recovery. The muscle spasm caused by the pain of an early unsupported movement or provoked by a clumsy post-operative manipulation may delay recovery for weeks by rendering the patient afraid to continue with his exercises. Subsequent unsympathetic treatment directed towards breaking down "joint adhesions" by force makes matters worse by increasing muscle spasm and antagonizing the patient. This is particularly true after the operations of synovectomy or arthroplasty, but it also occurs after fractures of the femur or over-enthusiastic manipulations of an arthritic knee- or hip-joint.

To lessen the pain of early post-operative joint function, and so secure the enthusiastic co-operation of the patient in the performance of his exercises, we have devised the "railed splint." This apparatus (Fig. 1, A) resembles roughly a Thomas splint hinged at the knee and hip. Proximally it is attached to a U-shaped support (B), from the base of which a single rail (C) runs distally, serving the double purpose of base-piece and rail. D is a clamp to secure the splint to the foot of the bed; E is a grooved wheel which runs along the rail C and can be locked at F; G is a metal loop with a rope-and-pulley attachment to a Balkan frame and a handle (H).

By pulling on H the patient can produce flexion of his knee- and hip-joints (Fig. 2). The range of movement can be gauged accurately by the patient, so that it is practically painless, and as he is in control of his movements he soon gains complete confidence in the apparatus. The wheel (E) reduces friction to a minimum and permits of free and easy motion. Genu recurvatum is prevented by the metal catch (I) placed just proximal to the lateral pulleys (J). In a short time the patient can obtain good range of painless movement, and as he can check th degree of flexion daily by noting the position of a coloure section of the pulley rope he is encouraged to proceed to sti greater effort in mobilizing the affected joints.

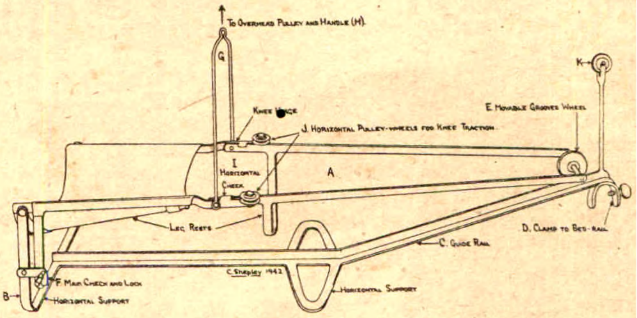

Fig. 1.—The railed splint.

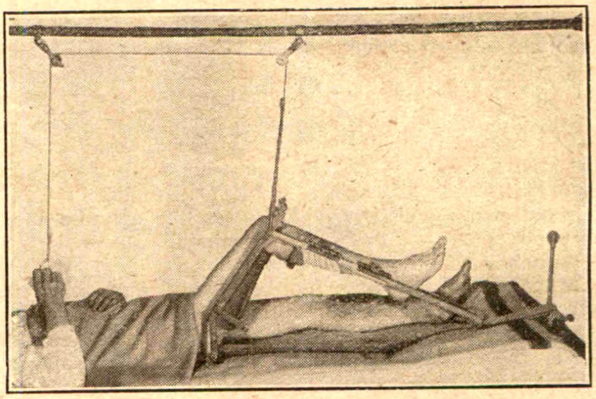

Fig. 2

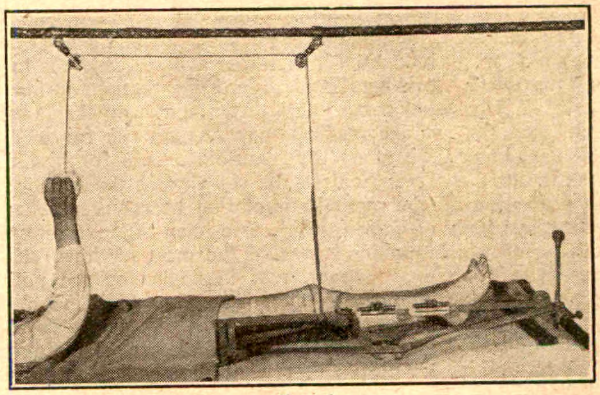

Fig. 3

When locked at F the splint is converted into a modifie Thomas knee-splint (Fig. 3). In this form it can be used i the early treatment of fracture of the femur by weight-and pulley extension over K. Countertraction is produced by th weight of the patient's body. Once a satisfactory position i obtained traction on a fractured femur can be maintained b means of the laterally placed pulleys at J, while the knee an hip are kept mobile. This is of importance in the later stage of treatment of most fractures of the femur or following th insertion of a Smith-Petersen pin for fracture of the femora neck, but it is of prime concern in the treatment of fracture of this bone in elderly arthritics.

The apparatus has been made for us by Messrs. Archibal Young and Son, Ltd., of Edinburgh.

SATURDAY NOVEMBER 28 1942

THE KENNY TREATMENT OF POLIOMYELITIS

If it were not for the more pressing medical problems of the war it is probable that much greater interest would have been aroused in this country by reports coming from the U.S.A. of the work of Miss Elizabeth Kenny. An earlier phase of Sister Kenny's work will be remembered by many readers of this *Journal*, for in 1938 we commented upon the report of a committee which had studied it.[1] This investigation was carried out at Carshalton under the auspices of the L.C.C., who had decided that Miss Kenny's claim to be able to prevent permanent paralysis should receive every opportunity of demonstration. Her work was sympathetically supported and considered. In those days little was heard of any revolutionary ideas about the pathology of poliomyelitis. The main points in her treatment of the acute stage were, and still are, the use of fomentations and hydrotherapy for the relief of pain, early passive movements, the avoidance of all splints, and a finely graded system of re-education. The committee of experts, while appreciating the value of hydrotherapy as practised by Miss Kenny, considered that very early movements, though harmless, were of unproved value. They agreed that, while it was possible under certain conditions to dispense with splints in the early stages of the disease, they did not approve of their entire abolition, and found that the mechanical methods substituted were inadequate. The committee certainly deprecated unintelligent use of prolonged immobilization, which was not regarded as good "orthodox treatment." In emphasizing the benefit of mobility Miss Kenny had done useful work.

Miss Kenny, who was apparently very pleased with her reception by the L.C.C., returned to Australia in August, 1938. In 1939 Starr[2] gave a report to the Minister of Health for New South Wales which did not appreciably differ from that of the Carshalton study. In March, 1940, Miss Kenny appeared in the U.S.A., and in the following June began work in the University of Minnesota, which later had the support of the National Foundation for Infantile Paralysis. As the result of the investigation of 50 patients treated in the early stage of the disease, workers in the University of Minnesota were satisfied that the length of time during which pain, tenderness, and spasm were present was greatly reduced, and that contractures caused by muscle-shortening during this period were prevented. There was an improvement in the general condition of the patient as compared with other methods of treatment during a comparable time. The National Foundation was advised to press for wide dissemination of training in the Kenny methods. In December, 1941, the *Journal of the American Medical Association*[3] made this cautious statement: "Adoption of the Kenny technique represents an elaboration of well-recognized principles," and, "If there is any revolutionary element it consists in its abandonment of early rigid splinting and the adoption of continuous and meticulous hydrotherapy and physical therapy to maintain the function of muscles, at the same time producing increased comfort to the patient."

There has been much that is confusing and uncritical in the writings of those who have taken up Sister Kenny's work: a "new pathology" is emerging which rationalizes[4] her theories on muscle spasm, mental alienation, and muscular incoordination, the fundamental features in which she is considered to differ from "orthodoxy." Dr. John Pohl[5] of Minneapolis, who was one of the first in the U.S.A. to interest himself in Miss Kenny's work, states that her principles were "designed for the management of specific findings which had never been previously recognized. Other methods have been aimed at the prevention of deformities, usually by splinting and immobilization rather than by treating the condition affecting the muscles which ultimately causes the deformities." "Miss Kenny treats the disease, while other methods only deal with the after-effects." Treatment based upon the three cardinal attributes mentioned above "can have nothing in common with the treatment designed for a disease exhibiting flaccidity of muscles and in which there is no recognition of incoordination." According to Pohl, Miss Kenny has shown that the primary lesion is spasm and that this causes contractures. Opposing muscles are reflexly removed from voluntary control ("mental alienation"), with resultant pseudo-paralysis. Spasm plus mental alienation results in further damage by causing incoordination. Pohl does not deny that paralysis depending upon involvement of the motor cells of the spinal cord may be present, but little is said about it, for he regards spasm as the most common and most damaging element in the involved muscles.

While not denying that there is room for improvement in the treatment of poliomyelitis and for further study of its underlying pathology, we believe that understanding will be enhanced by critical inquiry upon strictly neurological lines. So far this does not seem to have been done in the U.S.A. In the textbooks it is recognized that in poliomyelitis there is gross disorganization of muscular function with over-action (which is another way of saying spasm) of unparalysed muscles and incoordination, and that fibrillation takes place in partially paralysed muscles. The study of action potentials[6] is not, therefore, we feel, a very conclusive piece of work in support of Miss Kenny's theories. Also well recognized in the pre-Kenny literature is the fact that the disease affects more than the anterior horn cells of the spinal cord. Lesions have been reported in the posterior root ganglia, as well as in tissues other than muscle throughout the body. It is not true, as Pohl suggests, that other methods have been aimed only at the prevention of deformity rather than at the condition affecting the muscles, or that Miss Kenny differs from other people in "treating the disease." That mental alienation is no new idea is well shown by the following sentences from Jones and Lovett[7]: "Muscle training is fundamentally an attempt to restore a cerebral motor impulse to a muscle, an impulse which has been either impaired or lost during the acute stage of poliomyelitis. . . . If a muscle is apparently without any power, the patient should concentrate his attention on the attempt to accomplish the movement while it is performed passively." They knew all about incoordination, over-action or spasm of muscles, cerebral impulses, and the scrupulous care required for their protection and re-education. (A manual has now been produced by Drs. Cole, Pohl, and Knapp,[8] which in the U.S.A. is likely to be a standard guide for American workers in poliomyelitis. Their discussion of muscle physiology is incomplete and credits Miss Kenny with views about muscle action which at times are heterodox and at others are not Miss Kenny's at all, but those of well-known workers in kinesiology.)

That absolutely rigid splinting for acute poliomyelitis has not in the past been the orthodox procedure in the United States is shown by a study of the American literature and by at least one English commentator[9] on American practice. The emphasis, however, has been on rest, and that this has been overdone by some people has recently been demonstrated in a paper from Oxford in connexion with the allied problem of peripheral nerve injuries.[10] Nevertheless, we can scarcely agree with Dr. Lewin's statement in a recent paper[11] "that the Kenny treatment is evidently the last word in the management of the acute stage of infantile paralysis." We do feel, however, that Miss Kenny has contributed something which has stimulated many of our American friends to fever heat, and that with the wonderful opportunities they possess they themselves will, by modification and development, make an important contribution to our understanding of infantile paralysis. In this regard we feel bound to comment particularly upon a report from Dr. Steindler's clinic,[12] in which a more critical note appears. These workers suggest that the pathological concept must be changed from the old idea of a purely motor deficiency originating in a lesion of the anterior horn cells, but they believe that it would be a mistake to relinquish all methods and devices which customary treatment instituted for the preservation of muscles, for the control of pain, and for the avoidance of fatigue; they do not believe that all fixation should be abandoned. The final sentence of this article one suspects is by Steindler himself; it is certainly characteristic: "I believe that when we are convinced of the soundness of the newer clinical observations in infantile paralysis, the application of common sense and of general biologic principles will make apparent the proper road of conduct, free from orthodoxy and from radicalism."

In spite of the invention of new names for old ideas, in spite of the benefits of Sister Kenny's painstaking attention to detail, which differs not in principle but possibly in emphasis, we believe that some American workers are giving extravagant credit to her work and are detracting from traditional American orthopaedics, to which sufferers from infantile paralysis the whole world over owe so much.

WANTED: A NUTRITION POLICY

Complacency is a much overused word nowadays, but how else are we to describe the attitude of some members of the profession and of our Administration to the question of Britain's wartime nutrition? The recent statement[13] of Prof. Sydenstricker of the University of Georgia, U.S.A., has been taken to imply that there is ground for complete satisfaction. "Wherever he had been he had been agreeably impressed by the general appearance of well-being. So far he had seen no evidence of anything that should cause alarm. 'My outstanding impression is of the amazing and efficient job done by the Ministries of Food and Health in handling the situation.'" Prof. Sydenstricker is an eminent expert in this field and has considerable experience in the diagnosis of nutritional deficiency disease. We are fortunate indeed in having a man of his outstanding knowledge with us at the present time. But—and we ask this with the greatest deference—would it not be fairer to say that what Prof. Sydenstricker has demonstrated is that severe deficiency, of the type frequently seen in his native State of Georgia, is rare in England? He himself would be the first to admit that his observations are not intended to present a complete picture of nutritional status but referred mainly to the absence of signs of deficiency of vitamins of the B group, on which he is a recognized authority. More important, it is not possible to relate his findings to conditions before the war, because tests similar to those discovered and used by Sydenstricker are of only very recent origin. If, for example, we assume that only 5% of the population showed very mild signs of a specific deficiency, we might consider this as quite satisfactory; but if the incidence of this same mild deficiency before the war was 1%, the position is certainly far from satisfactory. It is of course equally true that if the incidence had previously been 20% we should, with justification, be highly gratified.

The point we wish to emphasize is that the effect of the wartime dietary on the health of the people can be judged only by a comparison of the present-day nutritional condition with that before the war. What emerges from a study of the few investigations in which such a comparison has been made certainly leaves no cause for complacency. Let us consider first the question of anaemia. Dr. Helen Mackay and her collaborators[14] have shown a disturbing fall in haemoglobin in women and children since the war, and at a recent meeting of the Nutrition Society Prof. Stanley Davidson[15] reported similar results among pregnant women and adolescents in Scotland. Medical students at Leeds show, according to Dr. Murray Scott,[16] a fall of haemoglobin of between 5% and 10% compared with pre-war levels. Nor is the increase in nutritional deficiency seen only in an increase of anaemia. There are several indications, for example, that the incidence of vitamin C deficiency is rising. Widdowson and Alington[17] have calculated that there has been an appreciable fall in the average intake of vitamin C. Saturation tests have confirmed this,[18] and there is also evidence that the increase in gingivitis, especially in the Services, is associated with a deficiency of vitamin C. Another indication that this deficiency is becoming commoner is the report by Dyke and his co-workers[19] that many cases of pernicious anaemia have recently been found to show a decreased response to liver therapy, which could be rectified by the simultaneous administration of vitamin C.

The nutrition of the child is probably of greater importance than that of any other section of the people. A mild deficiency for a year of, say, vitamin B_1 or vitamin C may produce in an adult suboptimal health or even frank deficiency disease; when a normal diet is resumed, however, there will almost certainly be complete recovery. But in a child there will be a failure of growth which nothing can completely restore. Medical men will therefore read with much concern the report of Dr. Milligan and Mr. Lewis-Faning on the physical and nutritional condition of children in wartime.[20] Continuing the excellent studies of the former worker on Glossop school children, these authors find that, between late 1940 and the end of 1941, there is in 11-year-old boys a diminished growth rate as measured by the increase of either height or weight, compared with the pre-war rate of children of the same age. They also determined endurance by measuring the time a child could support himself from a bar or could support a weight equal to his own on a pulley block. Both of these tests showed that the endurance was appreciably reduced during the period of observation. These results are certainly disconcerting and make it impossible to continue in our attitude of "all's well on the nutrition front."

The policy of the Ministry of Food has received praise from most nutritional experts. In particular, school children appear to be well provided for in their allowance of school milk, in their full ration of cheese and, in older children, of meat. On theoretical grounds there is little reason for criticism, except perhaps that the special physiological requirements of adolescents have not received the consideration they deserve. But as the *Times* has so well said recently, a food policy, however adequate on theoretical grounds, must be checked by its effect on nutrition; it cannot be thought satisfactory unless it is correlated with an effective nutrition policy. The proposed Nutrition Council, which we discussed fully in a leading article in the *Journal* of Sept. 26, would be able to organize and correlate nutritional surveys regularly throughout the country. As Milligan and Lewis-Faning say: "There is an urgent need for studies of this nature to be carried out elsewhere, especially to find out if growth is being retarded generally and if children are becoming prone to fatigue, as a situation of that kind can hardly be left undealt with."

A RARE CAUSE OF SUDDEN DEATH IN EARLY LIFE

Xanthoma tuberosum is characterized by nodules, tumours, and plaques situated particularly on the elbows, knees, and buttocks, and over the tendo Achillis and the tendons of the hands and feet. The cholesterol content of the blood is increased. Sudden death from cardiovascular involvement may occur. The hereditary nature of the condition was first noted by Wilks in 1868. Inheritance appears to be dominant, though incompletely so, for the disease not infrequently skips a generation, being transmitted, for example, from an affected grandparent through an apparently normal parent to an affected child. Hypercholesteraemia has, however, sometimes been noted in such apparently normal transmitters. The condition is rare, and, this being so, the absence of any undue frequency of consanguineous marriages among the parents of those affected is alone sufficient to rule out recessive inheritance. Bloom, Kaufman, and Stevens[1] have described in detail a family exhibiting a striking incidence of early deaths from associated heart lesions. They lived at Philadelphia, though of Syrian origin. The father and mother were outwardly normal. Of their 13 children 3 had died shortly after birth and 1 was an infant. Five of the remaining 9 had developed the syndrome at the age of 3 or 4 years; no fewer than 4 of them had died of cardiovascular disease. Another child, aged 8 years, had an abnormally high level of blood cholesterol, together with unmistakable evidence of a cardiac lesion, though without cutaneous involvement. Yet another, aged 4½, had hypercholesteraemia, though he was apparently normal in other respects. The father, though outwardly normal, also had hypercholesteraemia.

This family history emphasizes the point that it is possible for a gross outward manifestation to behave as an irregular dominant, while a less obvious but more fundamental underlying anomaly is directly and simply transmitted. In this case it may be that the hypercholesteraemia rarely if ever skips a generation, though the full syndrome does not always develop. This particular pedigree may, but probably does not, point to something more than simple dominant inheritance, for father and mother were second cousins; and, though the mother's blood was normal, 5 of her 7 step-sibs, blood relatives of the father also, had an abnormally high blood cholesterol. In the absence of a knowledge of other families, this pedigree would be puzzling; but, although it is possible that it does indicate something more than simple dominance, it is unnecessary to assume this. The authors have been led astray in supposing that 7 affected out of 9 probably means a real departure from the 1 : 1 ratio characteristic of simple dominance. Actually a discrepancy as great as 7 of one kind and 2 of another would arise purely by chance 92 times out of 512 on the average, or once in about 5.6 families. Without calculating the chances, however, the authors might have reflected that, in the case of another expected ratio of 1 : 1, the only surprising thing about a family of 7 boys and 2 girls or 7 girls and 2 boys would be the Victorian abandon of the total number.

The cutaneous manifestations are disfiguring and may be painful and disabling, but the most serious complication is the possible involvement of the cardiovascular system. One of this family at the age of 23 walked a mile and a half to church; fifteen minutes later she fell and died. At post-mortem myocardial degeneration and coronary sclerosis were found, death being attributed to the latter. There were orange-yellow deposits in the aorta and, in fact, in all the arteries of the body. A sister had a heart attack at the age of 8. When she was 14 she awoke one night complaining of slight pain. After sleeping till the morning she still complained of the pain. The mother left her for 15 minutes and found the child dead on her return. Another sister, aged 6½, awoke complaining of severe epigastric pain; she died in little more than an hour. A brother was taken ill at the age of 18. He was shocked and apparently in pain, and died in 2½ hours. The sole surviving child with cutaneous lesions was 11½; he presented signs of cardiac involvement. One of the other children with hypercholesteraemia also had an organic heart lesion. The authors suggest that attempts could be made to reduce the blood cholesterol by a suitable diet or by the administration of pancreatic extract, and that this might possibly control the tendency to cutaneous and vascular complications.

DIETHYLSTILBOESTROL FOR PROSTATIC CANCER

The treatment of prostatic enlargement with hormones has proved disappointing. The discovery that an oestrogen produced hyperplasia of the prostate and vesicles in male mice submitted to its action for a considerable time, and that they could be protected from this hyperplasia by simultaneous administration of male hormone, aroused hopes that prostatic enlargement in man would react favourably to injections of testosterone propionate. This hope has not been realized. Testosterone propionate has no effect on the enlarged human prostate, and we are now looking in another direction for help in dealing with this common trouble. In 1940 Kahle and Maltry[1] reported that they had obtained favourable results by treating with diethylstilboestrol patients suffering from innocent enlargement of the prostate. Since then this treatment has been extended to cases of malignant prostate, and two interesting papers[2] on this subject have appeared recently. The first, which deals mainly with clinical observations, is by P. J. Kahle, H. D. Ogden, and P. L. Getzoff, and the second, describing cytologic changes in the growths, is by J. R. Schenken, E. L. Burns, and P. J. Kahle. Although the number of cases treated with diethylstilboestrol is small—namely, 7—the results have been striking. In every instance this treatment brought about prompt relief of pain and urinary symptoms and a general improvement in the patient's health. Two of the cases were very advanced, and even bedridden. Both these patients were restored to activity in 4 and 6 weeks respectively after the beginning of treatment. The size and consistency of the primary growth were favourably affected, and a regression was witnessed in metastatic lesions. In 6 out of the 7 cases biopsy specimens were obtained by means of a resectotome, for microscopical examination before and after treatment. The changes in the carcinomatous tissues are described in the second paper, with excellent photomicrographs. In all 6 cases treatment was followed by regressive changes in the nucleus and in the cytoplasm of the malignant cells.

It is difficult to explain why oestrogenic substances should produce this effect on carcinoma of the prostate, or to decide whether they have a direct action on the malignant cells or work indirectly through the pituitary. The observations made by C. Huggins on the beneficial effect of castration in cases of malignant prostate are of interest in this connexion. It has even been suggested that, when benefit is obtained from deep *x*-ray therapy, it is due to accidental irradiation of the testes, with a resulting diminution in the secretion of male hormones. (R. D. Herrold has also reported an improvement in the clinical condition of patients suffering from carcinoma of the prostate, after the oral administration of diethylstilboestrol.) The authors of the paper under review prefer the intramuscular route as being more certain. One of their patients received as much as 503 mg. of diethylstilboestrol in 70 intramuscular injections of 5 mg. each and 153 injections of 1 mg. each. No ill effects were observed from the treatment, with the exception of a transient gynecomastia in 1 case. Although it is not claimed that a complete cure has been obtained by this treatment, the results have been gratifying. Carcinoma of the prostate has so far defied the best efforts of surgeons and radiologists alike, and any new form of treatment that brings even only alleviation of symptoms is to be welcomed. The follow-up study of these cases will be eagerly awaited.

ELECTRICAL RESISTANCE OF FACIAL SKIN

Measurements of the electrical resistance of the skin afford a simple means of defining the areas affected by sympathectomy, for slight heating in a hot-air bath greatly reduces the resistance of normal areas but not that of denervated areas; the line of demarcation is a sharp one. The latter areas correspond with those which do not sweat (shown by the starch-iodine test) at ordinary room temperature. Normal people show a high skin resistance in all parts of the body, except in well-defined areas on the face, in the axillae, antecubital fossae, and on the palms and soles. The electrical resistance is studied by means of two electrodes wired up with two 4½-volt dry batteries, a potential divider, and a micro-ammeter. One electrode—a half-inch disk of zinc sheeting covered with a paste of kaolin moistened with saturated zinc sulphate solution—is clipped to the ear; the other, movable, electrode is a zinc rod, held in the hand, terminating in a quarter-inch zinc disk which is applied to the skin. Before fastening the ear electrode in position a puncture is made in the skin there with a needle; this lowers the resistance to nothing, for it depends entirely on the skin. The electrical resistance shown by the ammeter depends, then, wholly on that part of the skin to which the movable electrode is applied. The apparatus is so arranged that when areas of high resistance are touched the pointer moves only a few degrees on the scale, while it moves right across the scale whe
low resistance are touched by the electrode.

Facial patterns of electrical resistance hav

War Medicine Series

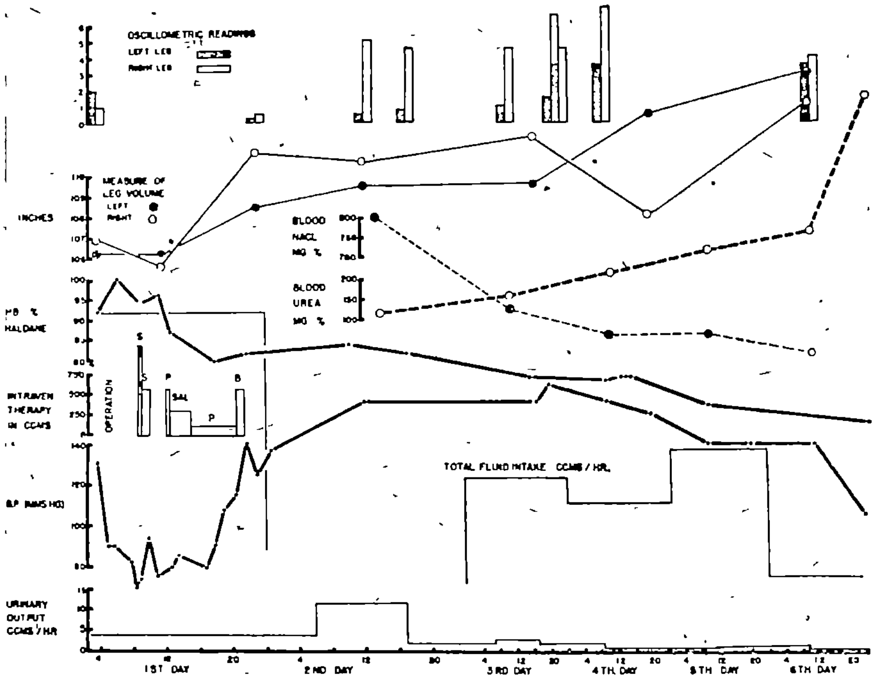
The paper printed below is based on a lecture which was one of a series recently given at the British Postgraduate Medical School, Hammersmith

CRUSHING INJURY

BY

E. G. L. BYWATERS,* M.B., M.R.C.P.

In the heavy air raids on London in the autumn of 1940 we attended some patients who had been pinned for several hours underneath the debris of their own bombed houses. Shock was present, which responded adequately to transfusion: the limb which had been compressed was found to be swollen and sometimes pulseless. To our surprise these patients developed renal failure with casts in the scanty urine and died in uraemia about the seventh day. This appeared to us at that time a new entity: it was described as such under the title of "Crush Injuries with Renal Impairment" (Beall *et al.*, 1941; Bywaters and Beall, 1941; Mayon-White and Solandt, 1941). Since then, however, we have discovered descriptions of it by German authors from the war of 1914-18. During that war Frankenthal (1916) and others directed attention to the local muscle damage, and it was not until later that the renal lesion was adequately emphasized (Minami, 1923). The condition had actually occurred in 1909 in people buried beneath the debris of the Messina earthquake, but as the relief expedition arrived on the scene a fortnight after the eruption, only the survivors with gangrene of soft parts were seen (von Colmers, 1909).



CLINICAL COURSE OF A CRUSHING INJURY CASE

Buried 6 hours. Note from above down:

(1) Return of circulation to legs as measured by oscillometer readings.
(2) Increase in leg volume measured by spiral bandage.
(3) Haemoconcentration and later haemodilution shown by haemoglobin level.
(4) Blood-pressure fall and restoration after transfusion.
(5) Decreased urine output with rising blood urea. Urine contained pigment granules and casts and failed to concentrate urea above 670 mg./100 c.cm.

Necropsy showed blanching and necrosis of muscle in both legs and a typical swollen kidney.

Apart from German books on military surgery, we have found no other references to it and no further records of cases. This is curious, since, even apart from the almost continuous warfare since 1918 somewhere in the world, such accidents do occur in the mining industry and have recently been described (McClelland, 1941). Since the first few cases in air-raid casualties were published the condition has been generally recognized here. Hospitals in the Emergency Hospitals Scheme of the Ministry of Health have been asked to notify cases to the Medical Research Council, which now has records of over 70 cases. It is on this group, through the kindness of the M.R.C. and its observers throughout the country, that the following observations are based. About 5% of air-raid casualties in an urban area may be of this type.

Clinical Description

The patient has usually been pinned by the limbs beneath heavy beams or pieces of masonry for a period of several hours. If seen soon after release from this compression he generally appears comparatively well, apart from other coincidental wounds, fractures, etc. Soon, however, he enters the first phase of shock, due to loss of plasma through the damaged capillary walls into the extravascular tissue spaces of the affected limb, which becomes swollen (see Chart). As a consequence, the haemoglobin and corpuscular content of the blood rises relative to the plasma, and vasoconstriction occurs to compensate for the decrease in circulating blood volume. During this first phase the skin is pale, cold, and moist, but the blood pressure is maintained at a nearly normal level. Later, however, vasoconstriction may become unable further to compensate for this leakage of plasma into the damaged area; the blood pressure then falls rapidly. This is the second phase of shock. If fluids such as serum, citrated plasma (plain or recalcified), and blood are given intravenously at this stage in adequate amounts the blood pressure can be restored to normal levels. This is the phase of recovery from shock. There may, however, be failure to respond to intravenous protein-containing fluids if the blood pressure has been allowed to remain at too low a level — below 80 mm. Hg—for too long a time.

Thereafter the general condition of the patient causes no anxiety until the first or second urine passed is noted to be bloody and to contain a pigment in solution similar in many ways to haemoglobin and giving a positive reaction to the benzidine peroxidase test. The urine also contains albumin, creatine, pigmented granular casts, and sometimes pigmented granules somewhat resembling erythrocytes; it is highly acid (pH 4.6 to 6.0) The daily output of urine may become very small despite an adequate fluid intake, but the pigment disappears as a rule after the second day.

Meanwhile, however, the damaged limb has swollen, is hard, tense, and cannot be indented. This swelling is usually progressive for the first four or five days, except possibly in cases associated with blood-vessel damage. The skin shows small petechial haemorrhages, erythematous wheals, and large blisters, related to the areas of direct contact pressure. These blisters are often thought to be the result of burns. They are not. They may occur in crops, related in time to the return of circulation to the damaged part. There is anaesthesia of the limb, often of a patchy distribution due to damage of the terminal nerve fibres, and sometimes of a nerve-trunk distribution. Paralysis, which may be of any severity, is usually present; in many cases arterial pulsation in the peripheral part of the limb is absent, the limb is cold and pale, and the onset of gangrene is to be feared. It is important to record the state of the circulation, which can be followed from time to time with the oscillometer. Sometimes Art and sometimes Nature will restore the circulation; often then the pulsation is greater on the damaged than on the sound side. Whether gangrene sets in or not, the severely damaged patient will continue in a peculiar state of mental apathy, alternating with phases of anxious and apprehensive awareness of his condition, until the end of the first week. During this time vomiting is a prominent symptom, and the blood pressure gradually rises to a level much in excess of the normal. The blood urea, potassium, and phosphate concentrations rise progressively, and the CO_2-combining power of the plasma falls. The urine flow is greatly diminished and, despite the high blood urea, there is failure of the tubules to concentrate urea and other solids, and also failure to reabsorb chloride, even though the blood chloride concentration is low: tubular dysfunction is therefore indicated. Pain in the loins (possibly evidence of stretching of the renal capsule) occurs not infrequently about the fourth or fifth day. Some patients have had severe abdominal pain and rigidity, and have been opened without anything definite being found. This symptom may be related to the kidneys.

---

*Beit Memorial Fellow.

The end of the first week is the critical period: in those patients who recover a sudden diuresis is seen, and thereafter the urinary output will rise gradually to very high levels. At the same time the blood urea level falls; the urea-clearance test (of van Slyke) may show improvement of tubular function, although this may not reach the normal level until several months after the injury. During recovery granular and epithelial casts may be noted from time to time in the urine. In the damaged areas skin and muscle may slough away; infection may occur. This is the "pressure necrosis" observed in base hospitals when the initial phases of the syndrome have passed unnoticed. Restitution fibrosis may occur if the damage is slight, a condition resembling Volkmann's ischaemic contracture.

In more severely damaged patients at this critical period some cardiac irregularity may be noticed, and electrocardiograms taken at this time show changes not unlike those seen in experimental potassium poisoning. The serum potassium level may be greatly increased, but it is difficult to say whether it is high enough to cause symptoms (as in the recent work on dogs by Hoff *et al.*, 1941). Too little is known about the balance between intra- and extra-cellular potassium at increased blood levels to be dogmatic on this point. However, we know that potassium is very soon and very easily lost from damaged muscle (Baetjer, 1935) and that it cannot be adequately excreted if there is severe renal impairment. Hoff *et al.* (1941) are of the opinion that, in man, death in uraemia from ordinary causes associated with a high terminal potassium is not a "potassium death," because the kidney can excrete this substance even in extreme oliguria. If, however, there is an increased flow of potassium into the blood stream from intracellular sources (and, in general, intracellular potassium is about 10 times as concentrated as extracellular potassium) it seems possible that this substance may be exerting toxic effects. Measures, such as insulin injection, directed towards the storage of circulating potassium might be found of value in cases in which there are indications of recovery of renal function.

Death occurs very suddenly: the patient may call out in great alarm, and be found pale and sweating, with dilated alae nasi. He may die within one or two minutes, or recover until a similar episode an hour or so later finally terminates his life.

Pathology

Changes are seen in the adrenals, muscle, vessels, and skin, and in the kidneys. There may be other traumatic lesions, such as fat embolism, contusion, or blast-lung. The muscles show one or more of the following types of change (Bywaters, Belsey, *et al.*, 1942):

1. Part of the muscle is blanched, unduly friable and necrotic, resembling fish flesh. The sharp demarcation line corresponds to the skin-pressure areas. This type is due to direct-pressure ischaemia.
2. The whole of the muscle is white and necrotic. This is usually seen in those muscles contained within tight fascial compartments, and it is thought that this necrosis may be due to rise of pressure within the compartment, with subsequent necrosis. It is for this type that fascia-splitting operations have been proposed.
3. The muscle may appear grossly normal, without pallor, but patchy necrosis of isolated fibres may be seen microscopically. It is this type that is associated with arterial spasm, due perhaps to periarterial haemorrhage or direct arterial damage, and sometimes associated with rupture of a main limb vessel without any prolonged crush. This type is thought to be due not to direct-pressure ischaemia but to vasogenic ischaemia. These changes depend upon the survival time and upon the extent of circulatory return.

The kidneys (Bywaters and Dible, 1942) are enlarged and swollen (except in patients dying early); they may show a white zone in the cortex, which is wet and glistening. Microscopically, the collecting tubules and the distal convoluted tubules contain a brown pigment material even in patients dying within one or two days of the injury: the proximal convoluted tubules show cloudy swelling and desquamation. In cases surviving for 3 to 4 days further changes are seen, consisting of areas of necrosis in the boundary zone and in the neighbourhood of distal convoluted tubules in the cortex. These are usually pronounced in the typical case ending fatally at the end of the first week from renal failure: there is oedema and cellular proliferation surrounding the large hyaline casts which are protruded into the interstitial tissue in these regions. Some polymorph infiltration may be seen within the collecting and distal convoluted tubules. The glomerular capsule may show cuboidal epithelium. This appearance is not entirely specific, since it occurs in certain other conditions. For instance, such casts, composed of haem pigment, occur after intravascular haemolysis if the plasma haemoglobin exceeds the renal threshold of 135 mg. per 100 c.cm. (Gilligan *et al.*, 1941). One of the most common causes of haemoglobinuria nowadays is mismatched transfusion. Not only is the morphologic lesion similar, with pigmented casts and, in certain cases, areas of focal necrosis, but the clinical course is also similar, with anuria and death in uraemia.

Pathogenesis

At first it seemed we might be dealing with some such haemolytic reaction, since our first cases had had serum and blood transfusion, but there were three reasons why this appeared improbable. First, the blood used was Group O; secondly, there was no clinical evidence such as chill, rigor, headaches, limb pains, vomiting, or jaundice following transfusion, nor was there any increased colour in the plasma, such as one would expect if any serious haemolysis had occurred. Thirdly—and this seemed the most cogent argument—no such reactions had occurred in any of our shocked and transfused casualties other than buried cases. Later we were to learn that this syndrome developed without any therapy other than "rest and quiet." Extravascular haemolysis, as in a haematoma, has been invoked to explain certain cases (Longland and Murray, 1941). In general, however, following extensive bruising of soft parts, the uptake of freed haem pigment is so slow that there is no rise above the renal threshold, and seldom even jaundice (except locally) unless there is associated liver dysfunction.

Discarding this theory, we were struck by the pallor of the damaged muscle at necropsy. Normal muscle owes its colour to a pigment called "myohaemoglobin," which differs from haemoglobin in several ways, since, although the iron-containing porphyrin group is the same, the globin portion is smaller. For instance, the spectral bands are 30 A.U. nearer the red, and the carbon monoxide span is 30 and not 60 A.U. There are three conditions in which myohaemoglobinuria occurs: perhaps the best known is paralytic equine myohaemoglobinuria. Five cases have been recorded in man, and we have seen a case recently, probably falling into this group: muscle necrosis is associated with myohaemoglobinuria, renal damage, and an increased blood potassium after exercise. In this disease, in the Haff disease, and in epizootic myohaemoglobinuria the muscles are blanched and are the seat of degenerative changes. The next step was therefore to identify this pigment in the urine (Bywaters, Delory, *et al.*, 1941). We were able to do this, using the Hartridge reversion spectroscope and comparing the pigment with myohaemoglobin extracted from perfused human muscle. Dr. Rimington confirmed our findings, and in addition demonstrated another important characteristic. As the molecule is one-quarter the size of that of haemoglobin, it will filter through smaller pores of semi-permeable membranes, and it will also sediment more slowly in the ultracentrifuge. Both of these things occurred, and they are of some clinical importance because they explain the curious fact that no pigment is seen in the blood stream: as the renal threshold is so much lower than that for haemoglobin, there is prompt excretion and no such accumulation in the blood stream as occurs with the latter pigment.

We regarded this identification of myohaemoglobin (Bywaters, Delory, *et al.*) as important not because it might be the cause of the renal failure (although that is possible) but because, like the creatinuria it was associated with, it definitely incriminated muscle damage. Cases had been cited (often, however, poorly investigated) in which there was no evidence of tissue damage other than lacerations. Since then we have found that crush lesions of trunk muscles often go unnoticed except for this indirect evidence of myohaemoglobinuria. Cases do occur, however, in which muscle necrosis follows not direct compression ischaemia but ischaemia due to arterial spasm or rupture of main arteries, and these cases may also develop renal failure (Bywaters, Belsey, *et al.*, 1942).

Was this pigment responsible for the renal failure? In the similar case of haemoglobinuria with renal failure following intravascular haemolysis the simplest theory is that the pigment blocks the tubules. Baker and Dodds (1925) demonstrated that in acid urine with high salt content the pigment changes to the less soluble acid haematin and is precipitated: with large and repeated doses under these conditions renal failure could be induced. Hence alkalinization of the urine (Bushby *et al.*, 1940) became the practice with all patients in whom a haemolytic reaction was to be feared.

Certainly, in these crush cases, oliguria, due to shock, and an acid urine are seen, and myohaemoglobin behaves similarly to haemoglobin under these conditions. Animal experiment has shown that in the rabbit, whose muscles contain no myohaemoglobin, muscle necrosis reproduces all the signs and symptoms of crushing injury except myohaemoglobinuria and renal failure. When myohaemoglobin in a quantity comparable to that excreted in human crush cases was injected into the rabbit acidified with ammonium chloride, we were able to produce death from renal failure. It seemed possible that partial blockage brought about a rise of intrarenal pressure, and this in turn led to irreversible renal failure.

The proof of this theory will lie in the prevention of renal failure in man by administration of alkali. As yet the validity of the theory is undecided, and the exact mechanism by which muscle necrosis produces renal failure has not been fully explained.

Associated Features

Crushing injury is often associated with other lesions which complicate both the clinical picture and the treatment. Of these the most common is haemorrhage, which may be internal or external. Haemodilution occurs after a variable number of hours, and if haemoconcentration due to plasma loss occurs at the same time the net change in haemoglobin may be *nil*. Fat embolism (Robb-Smith, 1941), often associated with fractures, may occur. The lung symptoms are manifest a few hours up to a day after the injury, and consist of pain in the chest, dyspnoea, pallor or cyanosis, and congestion. Systemic embolization occurs later, on the second or third day, with fat globules in the urine, petechiae, and a surly stupor or delirium. Thus uraemia has seldom an opportunity to develop unless the fat embolism is of a minor grade producing a delayed pneumonic process. Blast or concussion injury of lung is less common (Zuckerman, 1941): it may be present as slight dyspnoea with frothy blood-stained sputum and a ruptured drum or, later, lobar pneumonia. Another condition sometimes met with is carbon monoxide poisoning.

Differential Diagnosis

Oliguria may be due to oligaemic shock alone, to dehydration from vomiting or inadequate intake, to blockage by acetylsulphapyridine crystals, or to a mismatched transfusion: examination of the urine and blood, investigation of the blood pressure, and an intake chart are necessary to differentiate these conditions. Cortical necrosis has occurred after traumatic injury to the liver with necrosis. This is very rare. There is often a temporary retention of urine, disclosed as such by the passage of a catheter.

Haematuria from direct injury and haemoglobinuria from exposure to cold are differentiated by examination of the urine and the use of the spectroscope.

Limb-swelling may be due to a haematoma: the skin wheals are absent and there is no doughy feel to the muscle. Skin wheals may be mistaken for burns.

Prognosis

The prognosis depends on many factors—first, on the amount of muscle necrosis. If compression is for a shorter period than one hour the muscle survives unless arterial spasm prolongs the ischaemia. If longer than 4 hours, necrosis ensues. For periods between, tissue survival may depend on temperature. Curiously, periods of burial longer than 12 hours seem less serious than shorter periods, perhaps because only the least-hurt patients survive, perhaps because of a natural self-amputation and failure of the circulation to return to the part. The amount of necrosis in our animal experiments determined the height and duration of the haemoconcentration. Once the patient has recovered from shock, renal damage decides the outcome. Arm crushes have a better prognosis than those of the leg, perhaps owing to the smaller amount of muscle. The presence of other injuries adversely affects the result; the rapidity with which treatment can be started probably also does. About one-third of 70 cases have recovered; these were mostly minor cases without severe shock or uraemia—a class of case that is being increasingly recognized. However, a case has been seen (Bywaters, Belsey, *et al.*, 1942) in which the blood urea rose to 470 mg., and yet, without any treatment at all, on the critical seventh day a diuresis occurred and was followed by recovery. Claims of successful treatment have therefore to be very fully substantiated.

Summarizing, extent of injury, degree of haemoconcentration, oliguria, and blood urea rise constitute the four chief determining factors of prognosis.

Finally, one patient whom I saw through the kindness of Dr. Grant, whose patient he was, had drunk four pints of beer just before the establishment was demolished. They dug him out 11 hours later with both legs broken. In spite of a fairly high blood potassium level he recovered, but showed little haemoconcentration or uraemia. The possible protective action of this beverage might be worth investigating.

Treatment

The natural tendency under emergency conditions is to treat shock first, then the local limb condition, and lastly the renal failure on or about the third or fourth day, when signs of renal damage are obvious. Since it is possible that the renal damage occurs soon after the re-establishment of an adequate blood supply to the damaged limb, these three aspects should be considered in the reverse order.

1. Ample alkaline fluid (3 litres daily), by mouth preferably, or by rectum, intramuscularly or intravenously, must be given rapidly at the earliest possible moment, to produce an alkaline diuresis. If possible, this should be done while the patient is still trapped under the wreckage. We favour for ingestion an alkaline fluid flavoured with citrus juice or peppermint and glucose, containing sodium citrate and sodium bicarbonate, 3 g. of each to the ounce. Coffee or tea is also useful, and morphine should be given if required. For intravenous injection, isotonic sodium citrate (3.8%) or sodium lactate (M/6) should be used. Enough alkali should be given to make the urine alkaline: this will mean probably 30 to 40 g. daily or more by mouth, or a lesser quantity by intravenous injection. If tetany is induced, calcium gluconate should be given intramuscularly. Potassium salts must not be used. Sodium sulphate (2%) may also be injected intravenously in combination with the above measures to maintain urine output.

2. With the kidneys thus protected, it is safe to restore the circulation by combating shock, if this is present. Plasma or serum should be given, or, if there has been much haemorrhage, blood. A large quantity may have to be administered: so long as the arterial blood pressure remains low no harm need be feared. Saline is of no value. Overheating the patient is dangerous.

3. Local treatment to excise wounds and set fractures may now be undertaken. The limb may have to be amputated: if this possibility is considered on the first day it should be done soon, to prevent the absorption of autolytic products. A tourniquet may be useful. Amputation later may not save life, and should be done only if the limb is non-viable. Active measures to restore circulation in the damaged limb (only permissible once it is assured that there is an adequate alkaline diuresis) include elevation of the leg, incision of fascial sheaths, stripping of a damaged artery, or the use of alternate positive and negative pressure. Vasodilatation is best assured by giving alcohol and warming the body. The limb should be kept cool rather than hot, perhaps with bags of ice. This delays autolysis and decreases local metabolic needs in ischaemic tissue (Allen, 1938). Whether limitation of swelling by plaster-of-Paris (Trueta), tight binding, or inflatable rubber bags (Patey and Robertson, 1942) will do more than limit plasma loss into the leg (Duncan and Blalock, 1942) is uncertain. There is as yet no evidence that it will prevent renal damage.

It must be remembered that we are treating not only an injured limb but a human being who has passed through an exhausting and terrifying ordeal. Pain must be relieved and steps taken to see that the patient is comfortable in body and mind.

If by these means a fatal outcome, either from shock on the first day or from renal failure on the seventh, can be avoided, we have left a patient with severe muscle damage. These muscles may remain paralysed or may shorten, giving rise to Volkmann's contracture. They should be adequately splinted and exercised. If sloughing and gangrene occur, infection should be controlled.

In conclusion, this was until recently a little-known type of injury: we still know very little about its exact mechanism and how to treat it. Further observations on the effects of controlled and adequately followed treatment are needed.

CANCER RESEARCH IN YORKSHIRE

The Yorkshire Council of the British Empire Cancer Campaign, according to its sixteenth annual report, has carried through its last year's work without any further curtailment of research, and the programme has been about half that of a normal year. Apart from research, the Council continues to support the services of the radium officer and physicist in the radium department of Leeds General Infirmary, where a new deep-therapy apparatus has lately been installed, towards the cost of which the Council has granted £1,000.

The report embodies an account by Prof. E. D. Passey of some continuing work on experimental carcinogenesis in the department of experimental pathology and cancer research in Leeds University. The induction of pulmonary cancer in mice by intranasal administration of carcinogenic hydrocarbons has produced an unexpected result in the appearance of breast tumours in several experimental animals, suggesting that the genetic constitution of an animal is not a determinative factor in the occurrence of mammary cancer when some of the highly potent carcinogenic compounds are concerned. Another piece of work in this department has been an inquiry into the part played by heredity in the production of mammary cancer. The inquiry so far, which has included the investigation of the family history of 600 women in Leeds with cancer of the breast with a view to finding the incidence of cancer in their relatives, lends little support to the suggestion that heredity plays an important part in breast cancer in this country. Breast cancer does not appear to stand out as a family disease. Only in four of the 600 families was breast cancer reported as occurring in more than two relatives of the basal patient.

In the department of pathology and the field laboratory of the University of Sheffield Prof. H. N. Green reports attempts to correlate the results of investigations on bacterial growth and on the abnormal tissue growth of cancer. One aspect of this work, which is still proceeding, is the testing of chemical carcinogens, in view of their growth-inhibiting action on the whole animal, for a possible inhibitory action on bacterial growth. It is pointed out that if the mode of action of a carcinogen can be studied on bacteria the rate of progress in such studies may be speeded up enormously. Moreover, it is conceivable that there is no fundamental difference between the bacterial cell which has developed resistance to a cancer-producing agent and the tissue cell which in developing resistance displays, in relation to other types of tissue cell, the properties recognized as cancerous. A report from the same department describes two experiments designed to discover whether the epithelial proliferation induced by oestrogens in the breast and uterus and in the accessory sex glands would render them more susceptible to the action of a carcinogen which has no specific effect on these tissues. It appears that, provided the amount of carcinogen is sufficiently high to produce tumours with certainty in all the animals treated, or if the tissue is not susceptible to the carcinogen used, the effect of possible auxiliary or complementary factors in carcinogenesis is completely hidden.

VENEREAL DISEASE: APPLICATION TO SCOTLAND OF REGULATION 33B

The Department of Health announces that in the application to Scotland of the Defence Regulation dealing with venereal disease "special practitioner" is defined as a registered medical practitioner who provides treatment under a local authority's venereal disease scheme approved by the Secretary of State for Scotland; or a specialist in venereal disease in H.M Forces or Dominions Forces; or any other practitioner designated for the purpose by the Secretary of State for Scotland

The Secretary of State has made arrangements similar to those made by the Minister of Health (*British Medical Journal*, Nov. 21, 1942, p. 616), and copies of the general directions, forms, and notes may be obtained from the Secretary, Department of Health for Scotland, St. Andrew's House, Edinburgh, 1, or from the medical officer of health of any county or large burgh.

EFFECTS OF RADIATION ON X-RAY WORKERS

The Minister of Health has issued a circular (No. 2718) bringing to the notice of local authorities and voluntary hospitals a service which the National Physical Laboratory is prepared to render for testing the amount of radiation received by workers in *x*-ray departments. Although the service is intended primarily for hospitals, it is open to any person who uses *x*-ray apparatus or to any institution which employs workers who use *x*-ray apparatus.

The initial test (which should normally suffice) consists of each worker carrying a dental film in the breast or waistcoat pocket for a week. These films (one film per person) can be obtained on request from the Director, National Physical Laboratory, Teddington, Middlesex, together with a record card and instructions for use. On receipt of the exposed film and the record card, and a remittance of two shillings per film, the Laboratory will furnish a report. If the results are satisfactory, the test should be repeated, and fresh application made to the Laboratory, at three-monthly intervals. If the initial test shows unsatisfactory results, the Laboratory will be prepared on request to undertake the more elaborate investigations required The fee for any such investigation will be of the order of £5, together with any travelling or subsistence expenses incurred.

C. L. Prince and S. A. Vest (*J. Urol.*, 1941, **46**, 1129), who record the fifteenth genuine case of leiosarcoma originating in the prostate in a man aged 52, state that leiosarcomas form a definite entity and differ pathologically and clinically from other sarcomas of the prostate. They are of a somewhat lower degree of malignancy in the adult than other types of sarcoma of the prostate. The average duration of life in leiosarcoma of the prostate is 3.2 years in patients over 20 and 2¼ months in patients under 20. The authors' case is the first in which a pre-operative diagnosis was made and complete removal of the prostate carried out. The patient was completely well and free from metastases one year after the operation.

Correspondence

The Sulphonamide Problem

SIR,—Your correspondents Col. L. W. Harrison and Dr. P. W. Hamond (Oct. 31) have undoubtedly raised an important question with regard to the dangers of haphazard administration of sulphonamides in the treatment of gonorrhoea. There seems little doubt, however, that inadequate dosage and the consequent risk of the production of drug-resistant strains of organisms represent merely one feature of a wide and serious problem.

Surely the time has come for both the medical profession and the general public to recognize that the sulphonamides are, without exception, a potentially dangerous group of drugs: a group, moreover, which from being the boon of our age bids fair to become our curse. I include the general public because these drugs have been widely publicized and have a popular appeal. It is by no means unusual in these days to meet the question, "Aren't you going to give me M & B, doctor?" It would appear to be a matter of no little urgency that sulphonamide therapy be put on a really scientific basis, with due regard both to adequate dosage and to the risks involved. Anuria, haematuria, jaundice, agranulocytosis, leucopenia, and skin eruptions represent merely some of the more obvious side-effects one may be liable to encounter unless adequate precautions are taken, and some of them, moreover, despite every precaution.

I venture to suggest that the following rules should be applied in every case:

1. An established diagnosis; a raised temperature, of itself, being no indication for sulphonamide therapy, though it is, unfortunately, only too often considered as such in these days.
2. The appropriate member of the group to be chosen—i.e., sulphanilamide in haemolytic streptococcal infections, sulphapyridine or sulphathiazole in pneumonia, gonorrhoea, or meningitis, and so on.
3. Dosage should be adequate, our aim being to obtain an optimum blood concentration of the drug as soon as possible, total amount in any one course, however, not to exceed 25 grammes.
4. A high fluid intake with a careful check of both intake and output.
5. Routine administration of alkalis. Methylene blue is also useful.
6. Regular urine testing and blood counts.
7. The patient should be kept strictly in bed. This point is, perhaps, controversial, but it forms a natural corollary to Rule 3.—I am, etc.,

E. A. GERRARD, M.D., M.R.C.O.G.,
Royal Naval Auxiliary Hospital. Surg. Cmdr., R.N.V.R.

Child Health

SIR,—We have read with great interest Capt. Eric Townsend's letter (Nov. 7, p. 558) on child health, and are indeed glad that he has allowed himself "the expression of views that have long struggled for opportunity of outlet," and would assure him that the British Paediatric Association is in cordial agreement with his views and is engaged in taking steps which, it is hoped, will ensure their realization. Recently several subcommittees were set up by the association "to collect, collate, and co-ordinate" some of "the knowledge we already possess" of child health; some of the reports of these committees have already been made public and others will follow. Actually one of these reports was the subject of an annotation in the *Journal* of Nov. 14 (p. 582) under the heading "How much Vitamin D?" Other reports deal with neonatal morbidity and mortality, the pasteurization of milk and prevalence of milk-borne diseases, the effect of female labour on breast-feeding, day nurseries, child delinquency, the incidence of rickets, immunization against infectious diseases, and tuberculosis in childhood. In the necessary investigations the association has received valuable help and co-operation from medical officers of local authorities—some of whom have served as members of the subcommittees—help which is a happy augury for work in the future.

The British Paediatric Association has also drawn the attention of universities, medical schools, and examining bodies to the importance of adequate instruction and examination of medical students in paediatrics. In the view of the association, paediatrics should take the same place in the final examination in the United Kingdom that it does in America and Canada —i.e., it should form one of what would then be the four major subjects in the final examination.

The picture which Capt. Townsend draws of the future of the infant welfare clinic, in which the general-practitioner paediatrician takes a large share in association with the medical officers of the public health service, health visitors, etc., and a consultant paediatrician, is one which the association will strive with all its influence to bring to realization. Such an arrangement has, of course, also been envisaged by the Medical Planning Commission of the B.M.A., and we are convinced that only by some such scheme can the best welfare of the child be achieved.—We are, etc.,

LEONARD PARSONS,
President, British Paediatric Association
DONALD PATERSON,
Locum Secretary, British Paediatric Association

Proposed L.C.C. Medical School

SIR,—In your issue of Nov. 7 (p. 554) a summary is given of a report presented to the L.C.C. by its General Purposes Committee, and it is stated that the report is in favour of a statement of evidence to be given by the Council to the Interdepartmental Committee on Medical Schools, etc. The outstanding feature of the report, and, therefore, the one which is likely to cause most discussion and difference of opinion, is the proposed establishment of an undergraduate medical school founded upon the hospital services of the L.C.C.

I hope it will not be thought unbecoming for a former chief medical officer of the Council to express both disappointment and disagreement with this particular proposal. I do so because I am convinced from long experience of municipal and voluntary hospital work in London, including membership of the committees of two of the largest medical school hospitals, and also as one of the founders of the British Postgraduate Medical School, that the Council would be well advised to concentrate all its activities in connexion with medical education upon: (*a*) the further development of postgraduate medical education in London, and (*b*) the provision of still further facilities for undergraduate medical education in L.C.C. hospitals by closer and more intimate co-operation with *existing* medical school hospitals, particularly from the point of view of teaching.

This was the clearly defined policy of the Council for many years before war broke out, and in so far as co-operation with the teaching staff of the medical schools is concerned, I feel sure that all the deans of the medical schools in London will agree that the facilities referred to under (*b*) were developing most satisfactorily in a great variety of directions. Likewise the foundations of a first-class postgraduate medical school were well and truly laid, and only time for further developments was required when unfortunately war broke out. Moreover—and it is by no means an unimportant fact—the relationship between the Council hospitals and the voluntary hospitals of London was gradually growing into a practical working partnership and mutual understanding of each other's problems. The next desirable step would have been a scheme which we had in mind, whereby the teaching staff of the medical school hospitals would, wherever possible and desirable, be appointed to the consultant staff of the linked-up L.C.C. hospitals, thus overcoming certain practical difficulties in connexion with bedside teaching which were apparent to all of us. Unfortunately the outbreak of war prevented the development of this and many other desirable developments in connexion with (*a*) and (*b*).

More than three years have passed since my retirement from the Council's service, and therefore one cannot claim the same intimate touch with problems of medical education, etc., as in pre-war days. Nevertheless, I am still very strongly of the opinion that there is such an immense field for the development of postgraduate medical education in London, the metropolis of the Empire, that it seems to me to be a thousand pities for the L.C.C. to embark upon an entirely new policy, such as the creation of a municipal undergraduate medical school, instead of concentrating on postgraduate medical education and additional facilities in the Council's hospitals for undergraduates from existing medical schools. In both of these directions the Council can claim to have made a great contribution and to have rendered notable service to medical education, and, therefore, personally I deeply regret the proposed departure from the policy which characterized pre-war years.—I am, etc.,

Criccieth FREDERICK MENZIES.

X-ray Department at Health Centre

SIR,—Dr. J. V. Sparks (*Supplement*, Nov. 7, p. 57) makes the following comment on the proposal for "a small x-ray department" in a medical health centre: "This wording, which may be misleading, suggests to me either (1) that the department would be small or (2) that it would be equipped with apparatus of small power." Has he not missed the most important implication—i.e., that being a small department it would be equipped with a small-powered unit with which only simple examinations would be made, which would not require the services of an experienced radiologist? Surely there will be no question about the adequacy of the size of the department, but his opinion about the size of the unit may be challenged. The unit supplied is hardly likely to be less than the 30 mA unit. Now, in the hands of the expert this is a very efficient machine and would be adequate to do all the reasonable investigations at such a centre. But it is not the power or size of the unit which matters so much as the ability of the person using it, in both technique and interpretation. Generally speaking, the less efficient the unit the greater the ability necessary to use it, and not as suggested, for he admits that "the small-powered plant might give sufficient indication of the need for a further examination, but this might not be true for those cases where the initial findings were negative or presumed to be normal. Many examples could be cited of the dangers of an inadequate or incomplete examination." Surely it is only the person with experience and knowledge—the expert—who will know whether the examination has been adequate. Yet Dr. Sparks in a following paragraph sees no inconsistency in advocating miniature mass radiography as "a *new means* of detecting chest disease and possibly at an earlier stage," though the miniature photograph of the screen image for the detection of the early lesions is very inferior to the direct radiograph which can be taken with the 30 mA unit.—I am, etc.,

Birmingham JAMES F. BRAILSFORD.

Shock Treatment in Psychiatry

SIR,—In principle Dr. Jonathan Gould and his colleagues (Oct. 31, p. 530) are, of course, right to try to find out for themselves the merits of convulsion therapy in various types of schizophrenia. Statistically, however, we have already been shown that such investigations may be very unfortunate for a definite percentage of the recoverably schizophrenic patients treated in this way if the patients are thus deprived of insulin treatment at the earliest possible moment. There is a reasonable literature on this subject, and clinicians can already base their therapy on "prolonged and careful observation" over some years, as Dr. Gould wishes. For instance, the New York State Hospitals have treated over 1,000 patients suffering from all types of schizophrenia with insulin, have treated more than another 1,000 with convulsions, and have used over 1,000 controls. It was found that the patients treated with insulin did, as a group, three times as well as the controls, and that the controls did even better than the convulsion-treated patients. The ratio between the insulin recovery rate and that of the convulsion group was nearly seven to one (*Amer. J. Psychiat.*, 1939, **96**, 297). In England, Hemphill (*Lancet*, 1942, **2**, 152) has reported the poor results of electrical convulsion therapy in schizophrenia (only four of his seventeen early cases even did well). Another article is noteworthy in this connexion: 100 patients, mostly schizophrenics, who had failed to respond to convulsion therapy were subsequently treated with insulin. It was found that no less than 81% of those who could still be treated with insulin in the first six months of their illness recovered, despite the failure of convulsions, but this figure dropped to 25% of those who were not treated until six months to a year after the onset of the illness (*J. nerv. ment. Dis.*, 1942, **95**, 597). The danger of using convulsion therapy, whether chemically or electrically induced, in schizophrenia as a routine measure is that it may give a false sense of temporary relief by its ameliorating effect on the patient's mood, and consequently the use of insulin may in some cases be delayed until it is too late. Convulsion therapy should preferably be used in schizophrenia to get rid of depression, stupor, and inhibition, which may not be responding as well as the more fundamental thought disorder during the course of insulin therapy. Also, in certain cases of depression with a schizophrenic flavour a few fits may be all that is necessary to produce a quick remission. Such cases have not been classed as schizophrenia either in the American figures quoted above or in those of Hemphill, but it is conceivable that some of Dr. Gould's successful cases may fall into such a category.

Dr. Graf's letter (Oct. 24, p. 496) omitted an important point in discussing factors that would lead one to expect a favourable outcome for insulin treatment in schizophrenia. The essential thing is to have the patient early for treatment; given that, the personal skill of the therapist may, as in surgery, be the deciding factor. A reliable American clinic from 1936 to 1938 experimented with insulin treatment in schizophrenia, but the experiments were carried out by a variety of doctors who were taking no risks. Even then, 46% of the patients remitted when treated within the first year of illness. It became obviously worth while to employ a skilled therapist and give deep comas where necessary. The figures of immediate remission in this clinic have now risen to 79% in the same time-group (*Amer. J. Psychiat.*, 1941, **98**, 382).—I am, etc.,

Sutton, Surrey. WILLIAM SARGANT.

Treatment of Gonorrhoea

SIR,—Further to correspondence by Col. L. W. Harrison and Dr. P. W. Hamond (Oct. 31, pp. 528, 529), I would make a plea for local treatment of gonorrhoea by efficient urethral irrigations as an additional therapeutic measure, even though the efficacy of the sulphonamides has proved such a great advance in the treatment of this infection. The exigencies of wartime have not permitted an investigation to obtain statistics for cases treated by chemotherapy alone and by this means plus irrigation; but the impression is inescapable that relapses are more common if local treatment is omitted.

In the V.D. clinic at St. Bartholomew's Hospital we have treated during the past 3 years many cases of chronic urethritis—in the region of 100—which have resulted either from inadequate chemotherapy or even, in a considerable percentage of cases, from what is considered adequate chemotherapy but without irrigations. A large number of these cases were first infections—the greater number, in fact—and not complicated by local abnormalities such as meatal stenosis, hypospadias, etc., which might render efficient irrigation difficult.

The explanation of these relapses may be either that the natural immunity is given time to develop before chemotherapy is instituted—our practice being to irrigate for 4 or 5 days before giving a sulphonamide—or that the resultant disappearance of urethral discharge within 48 hours or so of the start of chemotherapy causes the patient to cease attendance and treatment, thinking, wrongly in the majority of cases, that he is cured. The future of such a patient is to act as a reservoir of infection, as in the case of the female, and as one who is open to all the later complications of gonorrhoea such as stricture, etc.,—I am, etc.,

St. Bartholomew's Hospital V D Clinic. K. R. OGILVIE.

Subcutaneous Ligature of Varicose Veins

SIR,—It is important, at a time when both the written and spoken word are being twisted all over the world for propaganda purposes, that we in our scientific literature should take extra care to check our statements. Dr. H. S. Russell (Oct. 31, p. 529) claims to be the first to use the subcutaneous ligature for the treatment of varicose veins. On April 26, 1941, Dr. Russell in an article stated that "the first case was treated [by this method] 18 months ago." His article led to a good deal of correspondence.

On July 12, 1941, I wrote that I had been using the method for several years, and drew attention to the advantages of using the hypodermic needle method of suturing, which, I said, was to the best of my belief first described by Dickson Wright. In the same issue of the *Journal* Dr. Norbet Schick stated that "subcutaneous ligature of varicose veins was first described by Velpeau and Schede and was soon given up. It was reintroduced and strongly favoured by Kocher (1916), who, in the case of widespread varicose veins, inserted 100 and sometimes more subcutaneous ligatures. Soon after Linser introduced the treatment of varicose veins by injection with sclerosing fluid; a combination of ligature and injection was employed by many surgeons." I therefore feel that Dr. Russell should not claim to be the originator of this method, nor of the use of the Dickson Wright method of suturing, since the correspondence which his article started, and to part of which he replied, brought out quite clearly that he could lay no claim to originality in the matter.

Nevertheless, I do agree with him that the method is a very good one, though by a more extended use of the empty vein technique I find it less necessary. A further refinement is the use of hollow-ended needles into which one can clamp a piece of kal-dermic or other suture material, so as to make it an eyeless suture needle. I obtained both the needles and the clamp from Thackray, and as the needle is curved this makes it easier to dip under the vein without enclosing much tissue or injuring the veins. Though I dispute his claim to originality in regard to the method, I do think that Dr. Russell has done a great deal to bring the method before the British medical profession, which is thereby considerably indebted to him.—I am, etc.,

Hove. H. J. McCurrich.

Palpation of the Spleen

Sir,—In his concluding article on malaria in wartime (Oct. 24, p. 489) Sir P. H. Manson-Bahr says: "There are various ways of performing palpation of the spleen, and new-comers have to learn the correct technique." As Sir Philip does not give details as to what ways he would recommend I may perhaps be permitted to describe a technique (called "Schuster's *Fechterstellung*" in the German-speaking countries) which is superior for detecting minor splenic enlargements to the ways one sees palpation usually performed. The patient lies flat, without a head-pillow, and half turned over to his right side; his left arm is raised with the forearm resting on the top of his head and his left leg is slightly flexed at hip and knee. The examiner, standing or sitting on the right side of the bed, facing the patient, puts his right hand, flat, on the left hypochondrium, the fingers just touching the costal margin, and he increases pressure gradually with the palm of the hand during the patient's deep expiration. The left hand lies centred about the posterior axillary line over the costo-lumbar region, at right angles to and pressing towards the palpating right hand. An attempt to palpate the spleen, as is so often done, with the fingers pressed in under the costal margin stimulates a guarding response of the abdominal wall which prevents perception of any but a markedly enlarged spleen; furthermore, exertion of pressure by the finger-tips blunts greatly the tactile sense of the finger-pads. This point is, of course, also of significance in the palpation of other abdominal organs. Finally, in severely ill patients a deep respiration can sometimes be evoked by letting the patient first hold his breath for a while. —I am, etc.,

Lambeth Hospital, S.E.11 Herbert Levy.

Purpura in Fulminating Meningococcal Septicaemia

Sir,—Dr. A. J. Watson's letter (Nov. 7, p. 558) referring to an earlier letter about the same subject by Dr. E. H. M. Milligan (Oct. 3, p. 405) and to Dr. I. S. Fox's memorandum (Aug. 22, p. 218) interested me as a haematologist very much. I can fully confirm Dr. Watson's findings on blood films. In 1933 a woman of about 60 years was admitted to the 1st Czech Medical Clinic of Prof. Hynek in Prague. She was unconscious, severely cyanosed, and her skin almost all over her body was covered with a purpuric rash and smaller and larger ecchymoses of deep red-blue colour. The white cell count showed a leucocytosis of 85,000, mostly neutrophilic with a strong shift to the left and fairly numerous monocytes, some plasma cells, and a few endothelial cells. Apart from very heavy toxic changes of the neutrophils and monocytes, I saw *intracellular* diplococci in monocytes and in some neutrophils. Platelets were present in fairly normal numbers. The patient, who fell suddenly ill the previous day, died one hour after my investigations. The post-mortem examination showed no special meningeal lesions, but bacteriologically the findings were conclusive for a meningococcal septicaemia. The purpuric rash and ecchymoses were conditioned by bacterial emboli causing numerous infarctions, the base of which was corresponding to the skin haemorrhages. A perpendicular section through these haemorrhages showed the typical triangular shape of an infarction.

As it is evident from this case—see also Naegeli and others—the haemorrhagic diathesis in meningococcal septicaemia is caused by bacterial emboli, and it is very unlikely that these severe fulminating cases with already developed bacterial embolisms could be influenced by sulphapyridine therapy as Dr. Watson suggests. The reverse would be the proof of the highest efficiency of chemotherapy.—I am, etc.,

Warwick Hospital. S. Varadi.

Anaesthesia for Tonsillectomy

Sir,—With reference to Mr. T. B. Jobson's article (Oct. 31, p. 512) on the question of the methods of removing tonsils, and confining myself to operations on children, it would seem to me that the essential point is not whether it should be done by guillotine or dissection, but whether one should use an anaesthetic which permits one to do all that one wants to do. Ethyl chloride is certainly not such an anaesthetic. With its use one is strictly limited as to the time at one's disposal, the surgeon being in effect told: "You have a few moments in which to get these tonsils and adenoids out, and to satisfy yourself that it has been adequately done. If you can't do this by the time the patient is coming round then it must remain undone." Such a state of affairs would not be tolerated by surgeons in any other branch of surgery where adequate alternatives were available.—I am, etc.,

Shrewsbury. E. Gordon Laurence.

Sedimentation Rate

Sir,—The letter of "Rural Practitioner" (Oct. 24, p. 497) rather puzzles me. He says that the sedimentin index estimated weekly or monthly reveals the patient's rate of progress, how long it will take him to get well, and whether treatment is making any difference, in addition to showing how ill the disease is making him. This is, in point of fact, the very information that we have been obtaining from the standard Westergren technique for the last twelve years or more in a large rheumatism clinic, so where the advantage of the sedimentin index comes in is a little hard to see. But perhaps I am misunderstanding him.

With regard to the technique that he employs, may I say that the back of a car on a morning round is not the place to ensure that the tubes are constantly maintained exactly vertical, and that, while I have made no experiments on the effect of vibration myself, one of the pioneers of the method who tried doing the tests in the train on the way home said that he could tell from his results whether he had gone home on a fast or a slow train.—I am, etc.,

Hayward's Heath J. W. Shackle.

Sir,—Mention of the blood sedimentation test seems invariably to invite a storm of criticism. That this should be is an index of the lack of agreement that exists on its clinical value. It is obvious that the position should not remain thus, and organization and publication of the recent researches on the subject are long overdue. The *British Medical Journal* is perhaps the most widely read medical journal in this country, yet since the introduction of the blood sedimentation test in 1917 barely half a dozen papers on it have appeared in its pages (and few of these were edifying). A survey of the literature in British, American, and Continental medical journals discloses that much of it is devoted to technicalities involved in performing and interpreting the test (sedimentin index, etc.), while its clinical side has been neglected. A comprehensive survey of the clinical value of the test would be generally appreciated. Probably the best such study is that of A. Rees Walton (*Quarterly Journal of Medicine*, Jan., 1933, p. 79).

"Rural Practitioner" carries a rack of bloods for the sedimentation test on the floor of his car. What effect does he think the jolting and vibration of the car will have on the readings, not to mention the inclination of the tubes when the car is going uphill or down? It is well recognized that even slight deviations of the tube from the strictly vertical give errors in readings as much as 40%.

The test has, however, its value in rural practice, where other laboratory and *x*-ray facilities are not available, so long as its limitations are fully appreciated. A normal sedimentation rate in a patient with back pain who is elderly and might have metastatic cancer is reassuring to the doctor. The rate is normal in subarachnoid haemorrhage and all stages of acute anterior poliomyelitis, which aids in the differential diagnosis from cerebrospinal fever, in which there is a sharp rise in rate within 6 hours of the onset. Instances of the value of the test are many, but unfortunately are little known or taught outside sanatoria.—I am, etc.,

Ballycarry, Co. Antrim WILLIAM CALWELL.

Control of Tuberculosis in the Home

SIR,—The Principal Medical Officer of the Ministry of Health has foreshadowed a drive in the direction of eliminating the scourge of tuberculosis in this country. The enormous benefit of mass radiography in detecting early cases should not blind us to the greater advantage of getting at the disease further back—namely, at the source of infection. There are still many patients seen at the tuberculosis clinics who cough without covering their mouths, still too many sufferers who live in undue intimacy with their families, still too little fresh air and sunlight in the homes of the afflicted, still great lack of nourishment in the homes of sufferers thereby lessening the resistance of those in contact with the disease.

And what of the psychological attitude of the companions of the patient in his home? The healthy contacts will have their resistance lowered by fear of catching the disease, and yet they must be warned as well as made to realize that if reasonable precautions are taken in the light of modern hygiene the risk to themselves is slight. Clement Dukes stated that "tuberculosis is more a *house* disease than an infectious disease," and this is probably a clue to control.

It has been said that the two most important factors in life are "courage and interest," and this would appear to be of tremendous value in arranging the life of the tuberculosis sufferer and his contacts.—I am, etc.,

London, N.W.11 L. S. WOOLF.

Sending Assistance to Bombed Towns

SIR,—We have read with much interest Mr. F. W. Willway's article (Nov. 7, p. 552) on sending assistance to bombed towns. As we are a hospital which has received outside assistance after an air raid we should like to mention some of the difficulties we encountered.

A detached point of view may be useful, but much more is required before any improvements can be achieved, as each raid will produce its own problems depending on the size and character of the town involved. It is obviously necessary to have some scheme prepared, but common sense at the time is much more important than the most meticulous paper organization. In a small and crowded town disorganization easily occurs, and matters such as communications, food supply, laundry, drugs, etc., can become a much more complicated problem than in a large city, the whole area of which is unlikely to be involved to the same extent in a single raid. Both of us have been working in the casualty services of the City of London throughout all the raids and are not entirely unacquainted with the effects of sustained raids on a large city.

We fully agree that a system of dispatch riders should be available from the onset of the incident, but we entirely disagree with Mr. Willway's "shock troops team." We feel that the sudden invasion of a hospital busy admitting large numbers of casualties by an unspecified number of helpers entirely unacquainted with the local conditions and resources will only add tenfold to any existing difficulties. We found that it was impossible to operate while the bombing was still in progress, and in our view it would be much better that the relieving team should arrive a few hours after the cessation of the raid, in order that preparations may be made to deal smoothly and efficiently with the casualties. It would be of great assistance if the hospital could know beforehand the number and composition of the relieving team in order that arrangements may be made for their temporary feeding and accommodation, and therefore we suggest that the number and composition of the relieving team should be made known and could be expected to arrive, even without notification.

It should be unnecessary to mention that one's temper after a raid is bound to be somewhat frayed, and a display of tact and courtesy by the relieving team would be much appreciated and would do much towards avoiding petty irritations, which may later become magnified out of all proportion. We agree with Mr. Willway that the relieving team should be replaced after 8 to 10 hours, and furthermore suggest that it should be practicable for them to return to their own home; this would make it unnecessary to provide sleeping accommodation as in our case, where a large number of people had to be fitted into small residential quarters. Mr. Willway mentions in his article about the medical staff retiring to bed on the arrival of the relieving team. We were not so fortunate, for besides air-raid casualties we had to deal with other matters which could not be done by strangers, and when, after 36 hours without rest, we wished to go to bed, we had first to evict some of the senior members of the relieving team from our beds, who had decided upon the same "sensible manœuvre"!—We are, etc.,

F. KOHN.
St Martin's Hospital, Bath M. H. HALL.

R.M.B.F. Christmas Gifts

SIR,—On Oct. 17 you very kindly published my appeal to your readers for the Christmas Gifts Fund. I sincerely thank those who have already responded, but I hope many more contributions will be sent as soon as possible. The sum required is over £1,000 and has to be raised early to ensure that the recipients have the gift by Christmas Day.

As I write this letter we are feeling cheered by the recent good war news; may I suggest that we should provide the means of cheerfulness and encouragement for our beneficiaries on Christmas Day. Please send what you can and soon.—I am, etc.,

1, Balliol House, Manorfields, THOMAS BARLOW,
Putney, S.W.15. President, Royal Medical Benevolent Fund.

Obituary

DONALD STEWART MIDDLETON, F.R.C.S.

The medical profession in Scotland has suffered a grievous loss in the death of Brigadier Donald Stewart Middleton, A.M.S., which took place on active service in England last month. Middleton, who was only 43 years of age, was one of the most promising of the younger surgeons in Edinburgh. He was actually born in Natal, South Africa, but his father was an Edinburgh man, and it was to Edinburgh Academy and afterwards to the University that Donald was sent for his education. He graduated M.B., Ch.B. in 1921, and adopted surgery, for which he had a special aptitude, as his branch of practice. Four or five years after qualifying he became Fellow of the Royal Colleges of Surgeons both of Edinburgh and of England. In 1932 he was appointed assistant surgeon to the Edinburgh Royal Infirmary, where his work was highly regarded, and much was expected of his future achievements. At a meeting of the managers of the Royal Infirmary on the day that the news of his death was received a warm tribute was paid to his memory by Mr. W. J. Stuart, convener of the Medical Committee, who said that by his death the Infirmary had lost one who was more than a safe surgeon, and who by his future distinction would have added to its prestige. Other appointments which he held were those of assistant surgeon to the Royal Hospital for Sick Children and surgeon to the Deaconess Hospital, Edinburgh. He was also gifted as a teacher and did excellent work as lecturer on surgery in the School of Medicine of the Edinburgh Royal Colleges. In more than one of the surgical textbooks he was responsible for sections on branches of surgery in which he was interested.

From 1936 onwards Donald Middleton had served in a medical unit of the Territorial Army, and when war loomed ahead he was made A.D.M.S. with the rank of colonel in October, 1938. His administrative ability was such that promotion was rapid, and in the month in which he died he was gazetted as a recipient of the Efficiency Decoration. His three brothers were all killed in the last war, in which he was himself too young to serve. The memorial service in St. Giles' on November 4 testified to the great wealth of friendship which in his relatively short life he had accumulated. Many tributes have been paid to his engaging personality, his exceptional charm of manner, his unselfishness and love of simple things, and his unusual endowment of common sense. He was fond of several outdoor sports, especially riding, and he was a keen angler.

Donald Middleton married in 1930 Sheila, the only daughter of Dr. J. R. Currie, lately Professor of Public Health in the University of Glasgow, and had a son and a daughter.

Joseph Stanley Kellett Smith, who died recently in Cheltenham after an operation, was born in Liverpool in 1870, and studied medicine at Liverpool University, qualifying M.R.C.S., L.R.C.P. in 1891, and taking his F.R.C.S.Eng. in 1895. After two years as demonstrator of anatomy at the University, he accompanied the British expedition of 1895-7 to Central Africa, whence he returned to take on his father's practice in Liverpool. In 1911 he practised electrotherapeutics at Eastbourne, and in the R.A.M.C. during the last war he was in charge of electrotherapeutics at Summerdown Camp. After the war he was superintendent of the West of England Convalescent Centre at Saltash until 1923. He took the D.M.R.E. in 1924, and went to Cheltenham, where he practised radiology and electrotherapeutics until a few days before his death on Sept. 23. He wrote several articles dealing with curvature of the spine, flat-foot, sacralization of the 5th lumbar vertebra, etc., and was hon. consulting radiologist to Tewkesbury and Burton-on-the-Water Hospitals, and a member of the B.M.A. Kellett Smith's vigorous and genial personality (writes a colleague) endeared him to all. He had a sound knowledge of surgery and he took infinite pains. He was always anxious to help any of his colleagues, and it was a pleasure to him to demonstrate a barium meal or an unusual fracture. He was the best type of Northcountryman, and stood always for the highest principles of the profession. His only son, who studied at St. Thomas's, is now serving in the R.A.M.C.

On Nov. 3 there passed away a physician who occupied a unique position in these times. It is not many men who throw over the practice of medicine to devote themselves to a life of pure study and contemplation. **Herbert Edward Izard** qualified from Guy's in the year 1896 and went to Cheddleton to study diseases of the mind and to Manchester for diseases of childhood. Thence he went to a general practice in East London. It was here that he began to think of even deeper problems, and the result was that Dr. Izard sought admission to the Catholic Church and to the Benedictine Order, and ultimately became a priest and a contemplative monk. He finally settled at Quarr Abbey, where he became the infirmarian to the Community. Nor did he ever lose interest in the advances of medicine, and he loved to learn from visiting doctors. His scientific training found an outlet in a staunch upholding of the theological aspect of psychopathological conditions. The *Journal of the Guild of S. Luke* was rarely without an article from his pen. He was in consequence a man much sought after by those in trouble. He knew both sides of religion, Protestant and Catholic: he knew both sides of life, material and scientific. He will be very much missed both by the Community with whom he had lived for the last twenty years and by many more in the world outside who came to him for his wise advice in their spiritual and even physical difficulties.—C. L. E.

We regret to announce the death on Nov. 3 after a long illness of Dr. **Lawrence Edwin Price**, who had been a leading figure in the medical and public life of Nuneaton. He was born at Port Tipton on March 29, 1879, the son of Edwin Price, M.R.C.S., and was educated at Bourne College, Quinton, and the University of Birmingham. After qualifying M.R.C.S., L.R.C.P. in 1904 he served as house-surgeon at the General Hospital, Birmingham, and then settled in practice at Nuneaton, where he became honorary surgeon to the General Hospital and held a number of public appointments, and was instructor and examiner for the St. John Ambulance Association. He was elected to the Nuneaton Borough Council in 1920 and after holding office as chairman of the Health, Maternity and Child Welfare Committees became Mayor in 1928-30. Dr. Price had been chairman of the Nuneaton and Tamworth Division of the B.M.A., and presi
Branch. During the last war he hel

Hospitals, Dr. Shemelovich, stated that the right kind of medical and surgical supplies were not being sent to Russia at present; that they were short of large quantities of sulphanilamide and its compounds and x-ray apparatus, and that a better exchange of the latest information between Russian, British, and United States research foundations and doctors was required; and whether these matters would receive urgent attention. Mr. LAW: No, sir; medical supplies and equipment are being dispatched to the Soviet Union on the basis of a list of requirements communicated officially by the Soviet Government to the British Government. With regard to the suggestion that a better exchange of information on medical matters between the two countries was required, Mr. Law referred Mr. Adams to an answer given to Mr. Harvey on Jan. 21, and added that the British Government would at all times be happy to give urgent attention to any requests for information or assistance from the Soviet Government.

Diphtheria

Mr. BROWN, replying on Nov. 17 to a series of questions on diphtheria, said he understood that general practitioners in Darlington were encouraged to send to the infectious diseases hospital any case in which diphtheria was suspected, whether clinically established or not, because of the great importance of administering diphtheria antitoxin as early in the disease as possible. During the last 7 years there had been about 800 such admissions, covering all age groups. Of these, 78 were found to be not diphtheria cases, 47 being diagnosed as tonsillitis, and the remainder as cases of bronchopneumonia, Vincent's angina, syphilis, scarlet fever, or measles. Six of the 78 cases proved fatal, and 13 of them were in immunized children. In 1940 and 1941, 61 and 163 cases respectively of diphtheria were notified from Darlington. The numbers of deaths classified to diphtheria by the Registrar-General and assigned to Darlington according to residence in 1940 were, up to 5 years, one; 5 years and over, one; in 1941, up to 5 years, two; 5 years and over, five.

In Southend, 568 children under 5 and 1,355 between 5 and 14 received a full course of immunization under local authority arrangements during the months January to June, 1941. No cases of diphtheria were notified among immunized children. Among non-immunized children 17 cases were notified. None of these cases was rediagnosed. Two deaths occurred among non-immunized children under 5.

Medical News

The Duchess of Kent has become President of the Tavistock Clinic (the Institute of Medical Psychology)

Major B. W. Rycroft, M.D., F.R.C.S., R.A.M.C., has been appointed surgeon-oculist to the King of the Hellenes.

The United States National Foundation for Infantile Paralysis has given a 300,000 dollar grant to Johns Hopkins University for a prolonged study of the disease. This is the largest single grant made by the Foundation since it was organized in 1938.

The Association of Scientific Workers is holding a conference on "Scientists of the United Nations and the War Effort" at Gas Industry House, 1, Grosvenor Place, S.W., on Dec. 5 (2.30 p.m.) and 6 (11 a.m.) under the chairmanship of Sir Richard Gregory, F.R.S., President of the British Association. Applications for tickets should be sent to the secretary, Foreign Scientists Committee, Association of Scientific Workers, Hanover House, 73, High Holborn, W.C.1.

At a meeting arranged by the Wireless Section of the Institution of Electrical Engineers on Wednesday, Dec. 2, at 5.30 p.m., Dr. G. E. Donovan will read a paper on "The Electrical Amplifying Stethoscope and Phono-electro-cardioscope." Members of the British Medical Association will be welcomed at this meeting, to be held in the lecture theatre of the Institution, Savoy Place, Victoria Embankment, W.C.

A revised list (No. 7, Sept., 1942) of treatment centres in Great Britain and Northern Ireland approved by the Minister of Health under the Public Health (Venereal Diseases) Regulations, 1916, has now been issued. It gives the times set aside at each centre for medical examination and treatment.

Dr. Cyril Banks, M.O.H. for Nottingham, was installed on Nov. 20 as President of the Society of Medical Officers of Health.

At the annual ceremony of nominating the sheriffs for England and Wales on Nov. 12 Dr. J. C. Henderson was nominated for Westmorland and Sir Edmund Spriggs for Denbighshire

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales,* except for the relatively large increases in scarlet fever 153 and measles 572, the notifications for infectious diseases were below those of the preceding week. The incidence of scarlet fever is now higher than at any time in recent years.

Measles fell slightly in London and the south-eastern counties, and in Wales there was a large drop from 403 to 295. The biggest rises were in Lancashire 150, Derbyshire 136, and Yorks West Riding 124.

Notifications of dysentery were half those of the preceding week. The outbreak in Caernarvon, which with 152 cases was responsible for the large rise last week, contributed only 5 further cases. There were 37 more cases in Yorks North Riding (Middlesbrough C.B. 34), the largest total recorded during the eight weeks the outbreak has persisted in this area. The only other totals of importance were London, 14 cases from six boroughs, and Durham, 14 cases from five administrative areas.

In *Scotland* a rise occurred in cerebrospinal fever, measles, and scarlet fever. Measles, with an increase of 87 due to the experience in the large towns, reverted to the level of a fortnight earlier. Cases of cerebrospinal fever were recorded in twelve areas, the largest centre of infection being the city of Glasgow with 13 of the 30 cases. A small general rise in the incidence of scarlet fever was reported from the western area of Scotland.

In *Eire* the epidemic of poliomyelitis persists, 18 notifications coming from thirteen areas. According to the daily press a serious outbreak of typhus has occurred in the district of Spiddal, Co. Galway: 3 cases were reported from this county a fortnight ago, and one in the preceding week. Up to the time of going to press, 13 cases have been notified and an area of 175 square miles has been isolated. It is stated that some contacts have gone "on the run" to avoid medical treatment and isolation. Special measures have been taken by the Ministry of Health to prevent the disease from spreading to Britain. A watch is being kept on sea and air ports and teams of doctors and nurses are ready to be called in case of need.

Small-pox

In the outbreak of small-pox in Edinburgh there have been 20 confirmed cases and 2 deaths. In one case, that of a girl, there was apparently no connexion with the other cases, which had a common source. A case of small-pox reported from Halfway, Lanarkshire, had its origin with the Edinburgh outbreak. At Cowdenbeath a schoolboy has contracted the disease but the source of infection has not been established; there appears to be no relation between this case and the outbreak in Fife or Edinburgh. A suspected case has been admitted to hospital in Perth.

Diphtheria

The campaign for immunization against diphtheria has not yet had any very large apparent influence on the trend of the incidence of this disease. Although the relatively big weekly fluctuations in the totals of notifications mask to a certain extent the differences between various years, there has been a tendency for the recent level of diphtheria to be below that recorded in the last few years. The notifications totalled in four periods of eleven weeks for the last six years illustrate this:

Weeks	1942	1941	1940	1939	1938	1937
1–11	9,969	12,435	7,820	13,034	18,160	13,077
12–22	7,854	10,230	7,511	8,844	12,333	10,332
23–33	7,382	8,808	8,379	8,861	10,457	10,247
34–44	9,551	10,217	12,306	9,698	13,540	15,270

During the 23–33 weeks of 1942 the notifications were approximately 1,000 fewer than in the next best year, but this advantage was largely lost during the 34–44 weeks, when 1942 was only 147 below the next best year. The position may be better than the figures would lead us to believe if the London experience can be applied to the whole country. In pre-war years, in London, an error of 30% occurred in the diagnosis of diphtheria, and since the war this has increased to over 40%.

Returns for the Week Ending November 14

The notifications of infectious diseases during the week in England and Wales include: scarlet fever 2,880, whooping-cough 1,155, diphtheria 940, measles 7,731, acute pneumonia 556, cerebrospinal fever 50, dysentery 148, paratyphoid 3, typhoid 13.

No. 44

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Nov. 7.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1942					1941 (Corresponding Week)

Rate per 1,000 total births (including stillborn)			34					46		

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes paratyphoid A and B for Northern Ireland.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE NO.—B.M.A. and *B.M.J.*: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent, London*; SECRETARY, *Medisecra Westcent, London*.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Treatment for Eruption on Scalp

J. A. M. writes: I have a woman patient with psoriasis of the scalp in which the whole scalp is covered with a very thick hard crust which, being entangled with the roots of the hair, is very difficult to remove and when removed leaves a raw painful surface. I have tried all the usual remedies without success. Could any reader suggest a simple method of removing this crust and/or treatment of the condition?

Dressing for Cancer of Breast

"DEODAR" would be grateful for suggestions for dressing a carcinoma of the breast which has ulcerated through the skin and is discharging copious clear fluid as well as pus. Wood-wool tissue, cellulose wadding, and gauze are being used, but something deodorizing would be welcome.

Intractable Urticaria

J. R. would be grateful for suggestions in treatment of an intractable case of urticaria. The patient, a healthy man aged 35, has been a victim for over 2½ years. He is unaware of any exciting cause. The swellings are very tender and painful and vary in size from a pea to an orange. They may appear on any part of the body. The feet, if involved, become so swollen as to prevent shoes being worn, and the lips become pendulous. The spots come out every afternoon after he has been on his feet since morning. Resting will not cause them to disappear. He must actually sleep for several hours before this occurs. He has failed to respond to treatment by elimination diets, colloidal calcium, autohaemotherapy, vaccines, ephedrine, and adrenaline. Protein tests were negative.

Income Tax

Locumtenent: Payment of Commission to Agency

"L.R.C.P." was engaged for a period in 1941 as locumtenent to one firm and later in the same year as assistant in another practice. He paid £23 commission to an agency in respect of these appointments. Can he claim to deduct the amount for income tax purposes?

⁂ There is no legal claim. The expense was incurred to obtain the appointments and not "wholly and exclusively and necessarily *in carrying out the duties*," though it was a natural preliminary thereto.

LETTERS, NOTES, ETC.

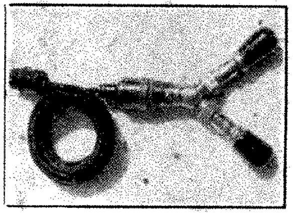
Sulphapyridine in Chronic Suppurating Conditions

Dr. A. FRY (London, S.E.25) writes: A man aged 59 was operated on on June 8, 1942, for an infected right hydrocele and right inguinal hernia. Post-operative hydrocele infection supervened, and the patient was kept in the hospital until July 13. The right scrotum was tender and painful, and there was a persistent discharging sinus. The discharge was thick and purulent. This continued until Sept. 29, and ordinary treatment—e.g., fomentations, etc.—had no effect. On Sept. 29 3 g. of sulphapyridine was given, and the following 6 days 2 g. was given each day. Twenty-four hours after the beginning of the administration of sulphapyridine the pain and discharge from the scrotum disappeared and the patient felt better. He resumed his work as a hairdresser on Oct. 10, and there has been no recurrence since. There was no bacteriological examination of the pus.

Dry Pleurisy

Dr. P. Mc[illegible]. ELDER writes: I read with interest Dr. J. Smart's paper on a new aspect of dry pleurisy (May 16, p. 604). The value of diagnosing those cases of dry pleurisy due to bronchiectasis has been rightly stressed by Dr. Smart, especially from the point of view of the ultimate prognosis and of fitness for employment in the Services. The only objection to routine bronchography would seem to be the danger of obscuring with retained lipiodol an early tuberculous lesion in the follow-up of the non-bronchiectatic cases?

Testing Skin Temperature Sensation



Surg. Lieut. T. DINSDALE, R.N.V.R., sends the following modification of Corner's skin temperature sensation tester (*Lancet*, 1932, 1, 732). He writes: It was designed to avoid the inconvenience of having to use test-tubes filled with water. A large lampholder has an "on and off" switch, which controls one of the two small 230-volt lamps; the other lamp does not light up. Both lamps are treated with cylinder black enamel. I wish to acknowledge the willing co-operation of Lieut.-Cmdr. (E) W. E. H. King, R.N., and also the skilful workmanship of Chief Electrical Artificer H. Frearson in the construction of this instrument.

Colour Film of Air-raid Casualties

This film (see *Journal*, July 18, p. 88) has now been shown to many hundreds of persons interested in first-aid work, and all over the country. Anyone still desirous to have it shown in their district are now invited to write to Mr. J. Magrill, 17, St. Quintin's Avenue, London, W.10, from whom all particulars can be obtained.

Corrigenda

Dr. HELEN MACKAY asks us to make two corrections to the report of the discussion on nutritional anaemia in children appearing at page 586 of our issue for Nov. 14. First, the work mentioned in line 10 of the second paragraph was done by Dr. Lucy Wills, Dr. Richard Dobbs, Lady Bingham, and Dr. Helen Mackay, and not by Drs. Wills and Mackay. Secondly, the sentence, "Of school children examined 90% had an average haemoglobin level of about 80%, and some 10% were lower than even the Davidson series of poor children before the war," should read: "Ninety school children aged 5 to 13 examined last winter had a mean haemoglobin level of 80%, which is about 10% lower than the value of poor Aberdeen children of similar age in Davidson's series."

MEDICINE 100 YEARS AGO

Extract from a leading article in the *Provincial Medical Journal* of November 26, 1842:

"Mr. Chadwick's report on the sanatory condition of the laboring classes contains an interesting chapter on the comparative chances of life in different classes of the community. We can readily understand that the various causes of sickness and mortality which prevail throughout the kingdom act with increased force upon the poorer orders, or are exclusively exercised upon them. The evil effects resulting from want of pure air, neglect of cleanliness, and inattention to various circumstances which predispose to or directly excite disease, are admitted as a general truth; but nowhere has the influence of these causes been so clearly and effectively demonstrated as in the report of Mr. Chadwick. Death, it has been said, is no respecter of persons, and the adage of the Roman poet, 'Pallida mors equâ pulsat pede,' &c., is familiar to us all; but death is like a dun; he knocks four times as often at the poor man's door as he does at the rich man's. The average duration of the poor man's life in a crowded, dirty court, may be *fifteen* years; while that of the rich man, who dwells in the neighbouring square, may be *sixty* years. The one class disappears from a scene of misery and privation before the other has arrived at manhood.

"The returns, from which Mr. Chadwick has derived his conclusions, appear to have been collected with as much accuracy as the nature of the inquiries admitted, and were generally corrected by local investigation of facts. They lead to conclusions of the most painful nature, mitigated solely by the reflection that the causes which determine such a sacrifice of human life are, in a great measure, under the control of wisely directed legislative enactments. At what period, whether near or remote, the attention of our Government will be seriously directed to this question, we cannot pretend to determine. It is one of pressing and vast importance; yet, while public clamor is raised against the destruction of a handful of barbarians, some three or four thousand miles removed from us, the loss of 80,000 of our countrymen, annually swept off by diseases, the great proportion of which are proved to be preventible, is unheeded, or treated with disregard."

INFECTED WOUNDS INVOLVING BONE TREATED WITH SULPHAPYRIDINE AND SULPHATHIAZOLE

BY

J. F. HEGGIE, B.Sc., M.B. **A. W. KENDALL, M.S., F.R.C.S.**
Surgeon Commanders, R.N.V.R.

AND

R. M. HEGGIE, B.Sc., M.B.
Lately Surg. Lieut.-Commander, R.N.V.R.

(From an R.N. Auxiliary Hospital)

Compound fractures caused by bomb splinters and other high-velocity particles and chiefly infected with *Staphylococcus pyogenes* were treated with sulphapyridine and sulphathiazole in addition to standard antiseptic and surgical measures. From our observations four main conclusions were reached: (1) Chemotherapy is a very necessary supplement to the surgical treatment of staphylococcal osteomyelitis in wounds. (2) Sulphathiazole is more efficacious than sulphapyridine in the treatment of these staphylococcal infections when the necessary blood concentration is obtained by oral or intramuscular administration. (3) Our results and experience in cases of staphylococcal infection established in bone indicate the advantage of combined oral and local administration of sulphathiazole when given at the time of surgical intervention, especially during radical surgical treatment. (4) Sulphathiazole applied locally, alone and unsupported by simultaneous oral administration, is of but limited value in the presence of slight or moderate, but established staphylococcal infection in wounds involving bone even on repeated application, and even after the bulk of the infected focus has been removed surgically.

In the absence of adequate simultaneous chemotherapy the surgical treatment of staphylococcal osteomyelitis complicating wounds may be attended by acute diffuse inflammatory changes locally and by varying degrees of bacteriaemia. Of the antibacterial drugs at present available for general clinical use sulphanilamide, sulphapyridine, and sulphathiazole can effect varying degrees of bacteriostasis. The superiority of sulphathiazole over sulphapyridine and sulphanilamide in such cases is in accord with the *in-vitro* finding that sulphathiazole is the most effective of these antibacterial sulphonamides and is 10 times more bacteriostatic against *Staph. pyogenes* than is sulphapyridine. The optimum times for the administration of sulphathiazole are pre- and post-operatively at sequestrectomy or at the removal of the entire infected focus—that is, when the amount of infection is so reduced that the concentration of free sulphathiazole in the blood and tissue fluids from oral administration, and the higher local concentration in the opened wound area from local application, will ensure maximum inhibition of the growth of remaining staphylococci for the time necessary for these organisms to be killed by the drug or dealt with by the body-defence mechanisms. The meagre results from local application alone are to be expected; for in such instances the high concentration of free sulphathiazole available for effective bacteriostasis (saturated solution in serum or exudate) is limited to a depth of only a few millimetres from the surface, since ready and free absorption of the drug into the lymph and blood streams results in a rapid fall in concentration to an ineffective antibacterial value in the deeper fibrous and osseous tissues of the wound in which staphylococci persist. The cases described below illustrate these points and other observations we wish to make.

Before admission to base hospital, active surgical treatment of a preliminary kind had been carried out, usually within 24 hours of injury; but this interval varied—2 to 3 days was common, 7 to 8 days was the extreme. Sulphapyridine in adequate doses orally, starting from the day of, or that following, the first operative treatment, may have accounted for the good general health and satisfactory progress in some cases found moderately infected on admission. In cases of severe injury the effect of sulphapyridine was less noticeable, but delay in primary surgical treatment probably contributed more to the detriment than sulphapyridine to the benefit of these. After admission cases requiring sequestrectomy received several courses of sulphapyridine to control recurring acute exacerbations of the staphylococcal osteomyelitis. It was in such cases that, after a "control" period of sulphapyridine therapy, sulphathiazole was given.

Persistence of Staphylococcus in Latent Foci

First of all it is necessary to recall and emphasize the persistence of pathogenic staphylococci in the deep and osseous tissues of infected wounds. This is an early manifestation which has its later counterpart in recurring acute exacerbations in the subacute and chronic phases of staphylococcal osteomyelitis. When, after surgical and chemotherapeutic treatment, granulating surfaces and exudates are bacteriologically sterile and the wound is healing well, and when, later, surgical measures prove necessary—e.g., trimming of a stump—organisms in latent foci may rapidly bring about grave local and constitutional disturbances. This case is an example.

Case 1.—Youth aged 17. Sustained three major bony injuries and burns of face and hands. Left foot amputated first day after injury on account of compound comminuted fracture of left tibia involving the ankle-joint. Stump became septic with sloughing (6th day). Admitted to hospital. *Staph. pyogenes* was the only organism recovered. Sulphapyridine 35 g. given in next 6 days. Improvement slow but steady. Clinical sepsis diminished. *Staph. pyogenes* last recovered 42nd day. Stump healed well, fibula protruded for 1½ in.; trimmed 94th day. Within 4 days the wound broke down over a fairly large area. Moderate pyrexia. Sharp anaemia: 93rd day—R.B.C. 4,800,000/c.mm., Hb 96%; 94th day—operation; 98th day—R.B.C. 2,900,000/c.mm., Hb 55%. The excised tissue yielded *Staph. pyogenes* in pure culture from the deeper parts of the granulations, the periosteum, and medulla of the fibula. The anaemia was due to the absorption of the α-haemolysin of the staphylococcal toxin.

4274

In a previously infected case such as this pre- and post-operative chemotherapy are necessary to secure, at the time of operation and later, an adequate blood concentration of antibacterial sulphonamide to combat transient staphylococcal bacteriaemia and to support a local application of the sulphonamide in providing an effective bacteriostatic concentration of the drug in the wound area against foci remaining after, or foci resulting from dissemination during, surgical intervention. Both oral and local administration should be undertaken in all such cases, for, although either alone may suffice, there are occasions when what may be regarded as "near misses" result from want of the combination. For example, in the next case; but for greatly increased dosage, oral administration alone would have failed to effect the necessary bacteriostasis.

Case 2.—Patient aged 38. Compound fracture lower end left tibia and fibula complicated by secondary haemorrhage and osteomyelitis due to *Staph. pyogenes* and haemolytic streptococci. Healing was slow, and was interrupted by acute exacerbations associated with sequestra. Amputation was decided. Sulphapyridine had not been tolerated well. Haemolytic streptococci were recovered until 49th day; *Staph. pyogenes* was recovered to time of operation and in the amputated limb from the deep granulations and bone. Pre-operatively, sulphathiazole 7 g. in 18 hours to within 2 hours of operation. Drug well tolerated.

Post-operatively, 1st 24 hours, sulphathiazole 9 g.; 2nd 24 hours, 8.5 g. During this period, however, the limb became painful and there was much redness and oedema of the stump; so in the 3rd 24 hours sulphathiazole was increased to 20 g. (4 g. 4-hourly). Acute nausea resulted; fluid intake was much reduced, but there were no urinary disturbances. Effect on stump striking and immediate. 4th day: Diameter of limb reduced by 1/2 in. 5th day: Nausea ceased; fluid intake increased to 5 pints. The serous discharge from the posterior aspect of the wound yielded *Staph. pyogenes* until 10th day. Wound epithelized by 17th day. Further progress uninterrupted. 18 months later: no exacerbations.

In this case we have concluded that the blood concentration of free sulphathiazole in the first 2 days (6.5 mg. per 100 c.cm.) was adequate to stem the bacteriaemia and to effect a certain measure of bacteriostasis locally, but the higher concentration of the 3rd day (8.6 mg.) and the concentrations of the 4th and 5th days (7.25 and 5.5 mg.) were necessary to control the local infection. A local application of 10 g. or thereabouts at the time of operation would have aided bacteriostasis in the stump at the site of amputation, and the much-increased oral dose of 20 g., well tolerated on the 3rd day, might not have been necessary. Alternatively, had the amount of sulphathiazole on the pre-operative and first post-operative days been 15 g., and 10 g. respectively, a further amount of 10 g. on the two succeeding days might have sufficed and no local infection developed.

These two cases stand in marked contrast. In the first, in the absence of continued chemotherapeutic measures, the amputation site became acutely and widely inflamed and broke down, pyrexia and acute haemolytic anaemia occurred, the staphylococcal infection persisted in the stump for 64 days, and healing was delayed until the 70th post-operative day (see below). In the second, using sulphathiazole, infection was controlled almost completely: from want of local application of sulphathiazole at the time of operation staphylococci persisted until the 10th day; nevertheless the degree of bacteriostasis obtained allowed the apposed flaps to heal and the scar to epithelize by the 17th post-operative day. There can be little doubt of the necessity for continued chemotherapeutic measures and for combined oral and local administration.

Superiority of Sulphathiazole in Staphylococcus Infections

It has been shown by Fleming's sulphonamide "impregnated strip" method in culture media that sulphathiazole is 10 times more bacteriostatic than sulphapyridine against *Staph. pyogenes.* The superiority of sulphathiazole over sulphapyridine in staphylococcal infections is fairly clearly demonstrated in the following case, in which the latter sulphonamide effected only partial, temporary amelioration, while the former, although given later, secured complete resolution. It could be argued, however, that in this case the number and virulence of the staphylococci had been reduced by previous treatment with sulphapyridine. Be that as it may, complete resolution occurred within a remarkably short time—10 days—after sulphath
was used, while with sulphapyridine therapy partial reso
only was recorded.

Case 3.—Midshipman aged 18. Sustained tracer
wounds of left leg with much muscle damage. First
treatment was on 7th day after injury; on the 12th a
abscess in leg was opened and muscle sloughs removed.
were two severe secondary haemorrhages, 15th and 21st
and mid-thigh amputation was done immediately afte
second. The patient was dangerously ill; blood transf
were numerous, but anaemia was marked. Pyaemia deve
on 25th day and showed some temporary resolution after
muscular sodium sulphapyridine therapy. Fresh met
foci appeared on 32nd day, but sulphapyridine orally w
minor value. Abscesses were opened at intervals until th
day. Metastatic foci appeared afresh on 57th day. S
thiazole was given orally. Temperature settled and foci sh
resolution within 10 days. Further recovery was uninterr
The patient returned to full flying duties and there we
exacerbations in the succeeding year. Sulphonamides
given as follows: 7th to 11th days, sulphapyridine, orally,
26th to 29th days, sodium sulphapyridine, intramusc
17 g.; 32nd to 35th days, sulphapyridine, orally, 30 g.; 5
62nd days, sulphathiazole, orally, 30 g. Despite the good
of oral sulphathiazole on the resolution of the metastatic
the stump exudate continued to yield *Staph. pyogenes,* the
organism present throughout. Sulphathiazole powder 1
applied locally, and was repeated 7 days later. *Staph. pyo*
was recovered until 20th day after application, but was bec
less haemolytic—1/10 to 1/160 of former value. This l
haemolytic value of the toxin was not permanent, and
recovered somewhat after 6 daily subcultures in ordinary

As in Case 2, the clinical improvement after sulphathi
therapy was much greater than anticipated, and in attri
the benefit to the sulphathiazole the result accords well
the *in-vitro* estimations of the relative bacteriostatic effe
these compounds.

Local Application

The effect of local application of sulphathiazole to a w
already infected is seen in the later treatment of the first
described, in which, after the acute inflammation of the s
had subsided, the local application of sulphathiazole
combined with immobilization in plaster, but unsupport
simultaneous oral chemotherapy.

Case 1 (continued).—Twelve days after stump was trin
temperature settled. Sulphathiazole powder 10 g. appli
raw areas and covered with vaselined gauze, and stump enc
in plaster. 16th day: Plaster changed, only *B. proteus* iso
47th day: Pain in stump, moderate rise in temperature; p
removed. *Staph. pyogenes* recovered from exudate then a
diminishing numbers for another 14 days—i.e., 47th to
days from application of sulphathiazole powder. Epitheli
70th day.

Had a second application of sulphathiazole been ma
the time of changing the plaster (16th day) the infection v
almost certainly have terminated by the 21st day or so.
the powder was seen to be absorbed on the 16th day—th
application was not sufficient to provide adequate concentr
of antibacterial substance for the necessary time in the
jacent tissues, from some residual foci in which reinf
of the wound area occurred. Later experience and estim
of sulphonamides in the washings of wounds showed
sulphathiazole is usually all absorbed at the 5th day.
case illustrates a certain minimum degree of effectivene
one local application alone to bring about bacteriostasis.
following case is an example of the effect of repeated ap
tions of sulphathiazole locally—again unsupported by s
taneous oral administration: this case was relatively
heavily infected at the time of treatment.

Case 4.—A man aged 25 sustained multiple wounds
a shell-burst. The concerned wound was penetrating:
fragment entered at the back of the left arm and came th
the shoulder. The wound became infected; for long there
discharging sinuses. The humeral head showed osteom
after fracture. Following increased pain in shoulde
sinuses were opened up and curetted; no sequestra were f
neither was bare bone seen. Sulphathiazole powder 10 g
packed in the wound. Cultures at 8th day after this were s
but *Staph. pyogenes* was isolated again from 17th day onw
There was an exacerbation on the 45th day; at a further o
tion on the 48th day the head of the humerus, mostly se
trum, was removed, the wound cleared out, and sulphathi

powder (10 g.) packed in wound. 3.3 g. sulphathiazole was excreted in the urine in the first 24 hours. Eleven days later *Staph. pyogenes* was recovered. The wound was re-dressed and sulphathiazole 10 g. in saline–tragacanth sludge used. The wound was examined, cultured, and repacked with sulphathiazole in slowly diminishing amounts (according as the volume of the wound diminished) at 5-day intervals. Healing was slow but satisfactory. Cultures at the first, second, and fourth intervals were sterile, but those at the third, fifth, sixth, and seventh yielded *Staph. pyogenes* in pure culture, but showing diminishing values for the α-haemolysin of the exotoxin in association with the continuous environment of sulphathiazole. The wound was sterile from the 51st day after the second operation and epithelized at the 60th day. Further progress was uneventful.

It will be noted that on each occasion when the bulk of the infection was reduced—after curettage and increased drainage in the first instance, and excision of the infected focus, the humeral head, in the second—the local application of sulphathiazole secured only temporary bacteriostasis: complete sterilization of the wound was not obtained. Sterilization—as judged by cultures from the wound surface and of exudates—occurred for brief periods. Had oral administration been combined with the first local applications at the times of surgical intervention, and the concentration of sulphathiazole in the blood and tissue fluids been thus higher at the time of "opening" of the foci, it is probable that bacteriostasis in deep-seated foci would have been more speedy and complete. And again, it is probable that results would have been more satisfactory *qua* speedy bacteriostasis had the wound been repacked on each 4th day rather than on each 5th, for the patient excreted on an average 3 g. of sulphathiazole daily, with the result that on each 4th day there was only 1 g. left in the depot (that is to say, when the depot was 10 g. in the first instance). Nevertheless we believe that this would have made but little difference so far as deep-seated foci were concerned.

One other factor to be considered regarding the local application of sulphathiazole in ordinary powder form to wounds is the probability that aggregation of particles and clumping occur, hindering solution and interfering with steady diffusion from the depot to the wound area. In Case 4 we made a suspension of sulphathiazole in a saline–tragacanth base. Later we used a glycerin–jelly base, part of the sulphathiazole being first dissolved in the glycerin: the remaining particulate part probably dissolved in the exudate resulting from the lymphagogue action of the glycerin, for in such instances we remarked, the absence from the walls of the wounds of the sulphonamide-impregnated fibrin "felt" sometimes seen when ordinary powder was used.

Effect of Sulphathiazole on Staphylococci

As regards the effect of sulphathiazole on the staphylococcus it will have been noted that in two of the cases described the organisms that were recovered at intervals from the wound areas to which sulphathiazole had been repeatedly applied were altered in character. The coagulase was never affected, but the haemolytic strength of the α-haemolysin was progressively reduced, first to 1/10 of its former value and later almost to zero, when estimated in the filtrate of a standard 24-hour broth culture. This effect was subsequently confirmed by suitable *in-vitro* experiments, using varying inocula of a subculture of the original virulent organisms and varying concentrations of the three sulphonamides. On further repeated subculture in broth from which all sulphonamides were omitted the strains showed recovery in α-haemolysin from almost zero to 1/20 of the original values shown by the virulent cultures when first isolated. It is probable that since the sulphonamides are believed (Fildes, 1940) to act by blocking the enzyme concerned with the utilization of *p*-aminobenzoic acid by the bacterium, the enzyme and the *p*-aminobenzoic acid are necessary to the *Staph. pyogenes* for the elaboration of the α-haemolysin of the exotoxin. We would also add that so far we have not encountered a strain of *Staph. pyogenes* which is sulphonamide-resistant.

Discussion

When wounds involve bone in which staphylococcal infection is established it is common to find repeated courses of sulphonamides necessary in treating the acute exacerbations of the local condition and possible systemic effects. This may be on account of either (i) the inability of the concerned sulphonamide *per se* to bring about complete or the minimum bacteriostasis necessary for healing, or (ii) the relative "inaccessibility" of the focus of infection to the drugs—or both.

The conditions under which the sulphonamides are actively bacteriostatic are now clearly defined. They are *active* only when in sufficient concentration in solution in the blood and other body fluids, 4 to 6 mg. per 100 c.cm. being a minimum level; and in this regard it should be noted that as their solubility in serum and other fluids varies, sulphanilamide being the most and sulphapyridine the least soluble, so also will the rates of absorption and the eventual fluid and tissue concentrations vary. In turn these variations will modify the effective bacteriostatic concentration resulting from the use of a given sulphonamide, for these substances vary also in their antibacterial effect, sulphathiazole being 10 times more bacteriostatic than sulphapyridine, and sulphapyridine in turn 5 times more active than sulphanilamide. Thus the absolute or resultant sulphonamide-bacteriostasis effected at any time is a function of the amount, solubility, and antibacterial index of the particular sulphonamide prescribed. The sulphonamides are *inactive* in the presence of large numbers of organisms and pus cells, and the disintegration products of these and of the tissues and fluid exudates.

The mode of action of the sulphonamides is now fairly well understood. They are directly antibacterial or bacteriostatic and inhibit the growth of organisms by competing with one or more of the essential growth-promoting substances (e.g., *p*-aminobenzoic acid, which is closely related chemically to sulphanilamide) for the enzyme or enzymes concerned with the utilization of these. The presence or absence of growth depends on the relative concentrations, and is proportional to, for example, the ratio of the growth-promoting *p*-aminobenzoic acid to the antagonistic or growth-inhibiting sulphonamide. Certain concentrations of the sulphonamides are thus prerequisite; but, even when obtained, the degree of bacteriostasis effected is dependent on the amount of neutralizing growth-promoting substances present, and these relatively simple chemical substances which promote growth are found in the disintegration products of tissues, pus cells, organisms, and fluid exudates. In the tissues the sulphonamides diffuse fairly freely and relatively quickly, and so from any established depot in a wound the concentration gradient in adjacent tissues shows a steep fall as the drug is absorbed into the general circulation. Again, the concentration in any tissue is a function of the water content, and consequently is lowest in fat, bone, and fibrous scar tissue.

All these things considered, it is perhaps obvious that, in the requisite concentration, this group of drugs will be more effective in cases of slight to moderate rather than in severe septicaemia, and early rather than late in pyaemia; and results will be more favourable *qua* bacteriostasis in the milder forms of these conditions than in cases of established localized infections in which the number of organisms may be relatively great and in which in addition there is serous exudation, a well-developed round-cell infiltration, and granulation and fibrous tissue. Thus, for example, it is agreed that, using sulphapyridine, it is easier to secure a successful result in the treatment of pneumococcal pneumonia than in lung abscess complicating that condition.

Similarly, having regard to the steep diffusion gradient, number of organisms, leucocytic infiltration, and fibrosis of the healing process, the *local application* of sulphonamides to wounds infected deeply would be expected to be of relatively little value. We have noted much delay, failure even, to secure bacteriostasis in wounds in which bone is involved and in which there is subacute or chronic osteomyelitis with sclerosis. The reappearance of the staphylococcus in exudates from such deep foci has been common. In this type of case it has been much easier to effect bacteriostasis or delay the reappearance of the organism by using local applications from the time of sequestrectomy or amputation, when the wound has been opened up or the bulk of the focus removed, than from a later date when infection has reappeared, say, 1 to 5 weeks after operation, when granulations are well formed and fibrous healing is proceeding apace in the depths, and when 5 or even 10 local applications at intervals have been necessary to obtain a measure of bacteriostasis, which even then may be only temporary.

And as, according to the example cited, it is easier to treat to a successful conclusion the pneumonia from the outset than the complicating lung abscess later, so in cases of infected wounds involving bone it is prudent to employ full chemotherapeutic measures at the time of full surgical treatment rather than later, when sequestra and sinuses may have formed in association with established infection. Full surgical procedure is of first importance, but we would emphasize that in cases of the kind considered here the pre- and post-operative administration of a sulphonamide, preferably sulphathiazole, is equally essential, and should be supplemented by local application, especially when many fascial planes have been disturbed or there is much tissue damage. For minimum pre-operative medication, 6 g. of sulphathiazole within 4 hours yields a blood concentration of 4 mg. per 100 c.cm., so that intramuscular and intravenous routes are not always necessary to supply the immediately available sulphonamide requisite in the blood and tissue fluids.

There is little doubt that sulphathiazole should replace sulphapyridine, both orally and locally, in the treatment of such cases of staphylococcal infection, for this drug is better tolerated and has a greater bacteriostatic action. Further, adequate oral administration of sulphathiazole should be continued as necessary, so that essential tissue-fluid concentrations are present when multiplication of organisms occurs or is likely to occur, thus ensuring that bacteriostasis is sufficient to permit the several body-defence mechanisms to operate unhindered or in conditions as favourable as possible.

Comment

While the treatment of infected compound fractures in wounds is essentially surgical, the role of the sulphonamides must not be forgotten or ignored. Sulphathiazole particularly is a valuable supplement. Given orally and locally at the time of major surgical measures, it provides the desired maximum bacteriostatic action when and where the diminished remaining foci of infection are most open to successful attack.

Since staphylococcal osteomyelitis is likely to be a not uncommon feature of many severe wounds sustained in this war by civilians and Service personnel alike, it behoves those concerned with early treatment to ensure that surgical treatment is adequately supplemented by chemotherapy so as to prevent the establishment of infection in bone, the treatment of which is notoriously difficult.

Summary

Sulphathiazole is more efficacious than sulphapyridine in the treatment of wounds with compound fractures that have become infected with *Staph. pyogenes*. The necessity for pre- and post-operative chemotherapy with this sulphonamide is stressed, as is also the combination of local with oral administration, especially at the time of radical surgical treatment. Sulphathiazole applied locally unsupported by simultaneous oral administration is of little value in the treatment of established infections of the kind discussed. Four cases are described illustrating these observations.

Strains of *Staph. pyogenes* recovered from our cases showed diminution of the α-haemolysin production but no alteration in coagulase in association with a local environment containing sulphathiazole. No sulphonamide-resistant staphylococci were encountered.

Our thanks are due to the Medical Director-General of the Navy and to Surg. Rear-Admiral H. E. R. Stephens, R.N., for permission to record these cases. We are indebted to Messrs. May and Baker Ltd., who kindly supplied the sulphathiazole used in the treatment of our early cases; and to Sick Berth Chief Petty Officers F. C. Prince and A. R. Woodman for technical assistance.

Fildes, P. (1940). *Lancet*, 1, 956.

J. Lusser (*Ann. Pediatr.*, 1942, **152**, 226) records his observations on 1,000 cases of scarlet fever at the children's clinic at Basle during the period 1930–40, 368 of which had relapses. 127 of the latter had recurrent eruptions. The second or third attacks usually had a mild course. The ages of the patients ranged from 1½ to 15 years; the incidence was highest between 4 and 15, while young children were less frequently attacked.

VENOUS PRESSURE DURING VENESECTION AND BLOOD TRANSFUSION*

BY

J. F. LOUTIT, B.M., M.R.C.P.
M. D. MOLLISON, M.B.
AND
E. D. van der WALT, M.B., M.R.C.P.

In man few observations have been made on the changes in venous pressure during the withdrawal and administration of blood, although the effects during the intravenous injection of crystalloid solutions have been investigated (Altschule and Gilligan, 1938; Murphy, 1941). In the present paper observations of venous-pressure changes have been made upon healthy individuals during venesection, and upon unselected hospital patients during the administration of blood. As an extension of this work similar observations were made during the transfusion of a number of patients suffering from pulmonary disease: in this group the vital capacity was measured before, during, and after transfusion. In all cases preliminary and final arterial blood pressures were taken, the pulse and respiratory rates noted at frequent intervals, and any change in the clinical condition of the subject recorded.

The venous pressure was estimated by the direct method, using a modification of the original Moritz and von Tabora (1910) technique. A stand was made with a backboard, to which the vertical arm of the manometer was clamped. The crosspiece rested on a horizontal ledge attached to the backboard. The backboard-and-ledge system was easily adjustable to different heights. In place of the reservoir a 30-c.cm. syringe, also resting on the horizontal ledge, was fitted to the crosspiece. By means of this syringe the manometer (7 mm. bore) was filled with 3% sodium citrate solution, and thereafter was flushed with this solution when required. The reference point taken was that recommended by Lyons *et al.* (1938)—an arbitrary point, with the subject supine, 10 cm. above the posterior surface of the thorax. The arm used for the venous-pressure estimation was abducted to an angle of 45 degrees. Where necessary, to prevent venous spasm a hot-water bottle was placed underneath the arm. Warm citrate solution was used throughout. An intradermal injection of local anaesthetic was given before all venepunctures.

An antecubital vein was chosen. A 16 s.w.g. intravenous needle was then inserted and connected with the manometer. If the needle was well in position the fluid in the manometer fell rapidly at first but later more slowly until equilibrium of pressure between the fluid in the manometer and the blood in the vein was reached. At this point there were minor respiratory fluctuations, either spontaneous or easily induced by deep breathing and occasionally pulse transmissions. Approximately 1 to 5 minutes were allowed to elapse before proceeding further, to ensure a steady base line of venous pressure. Throughout the experiment a rapid return of the manometer reading to the original level, after the apparatus had been flushed with fresh citrate, was regarded as the best criterion of patency of the system. In 4 cases venous spasm resulted in unsatisfactory readings and these records had to be abandoned.

Venesection

To minimize anxiety in the subject only donors previously venesected were chosen. In all cases complete rest for 10 to 15 minutes in the supine position was imposed, to allow the blood pressure and pulse rate to become stable. The venous pressure was then determined. Venesection with a 10 s.w.g. intravenous needle was performed on the opposite arm. A sphygmomanometer cuff maintained at a pressure of 60 to 70 mm. Hg facilitated the flow of blood. The average time taken to collect 430 c.cm. was 4 minutes. The venous pressure and pulse rate were recorded after 100 c.cm., 200 c.cm., 300 c.cm., 400 c.cm., and 430 c.cm. of blood had been withdrawn. In most cases the venous-pressure readings were continued at 5-minute intervals for 30 minutes after venesection.

---

* A report to the Medical Research Council from the S.W. London Blood Supply Depot.

In 19 of the 20 cases the initial venous pressure varied between 60 and 145 mm. H_2O. In one very obese woman the pressure was 167 mm. H_2O (Table I). In every case there was a fall in the venous pressure during bleeding, varying from 13 to 80 mm. H_2O, with an average of 43 mm. In most cases the venous pressure showed a fall after 100 to 200 c.cm. of blood had been withdrawn, and it continued to fall until the end of the venesection. After venesection the venous pressure rose gradually, but in none of the cases did it return to the original value within 30 minutes. The changes in the blood pressure and pulse rate were variable and not related to the constant fall in venous pressure.

TABLE I.—*Effect of Venesection on Venous Pressure, Blood Pressure, and Pulse Rate*

Case	Venous Pressure (mm. H_2O)			Blood Pressure		Pulse Rate	
	Before Venesection	After Venesection	30 min. Later	Before Venesection	After Venesection	Before Venesection	After Venesection

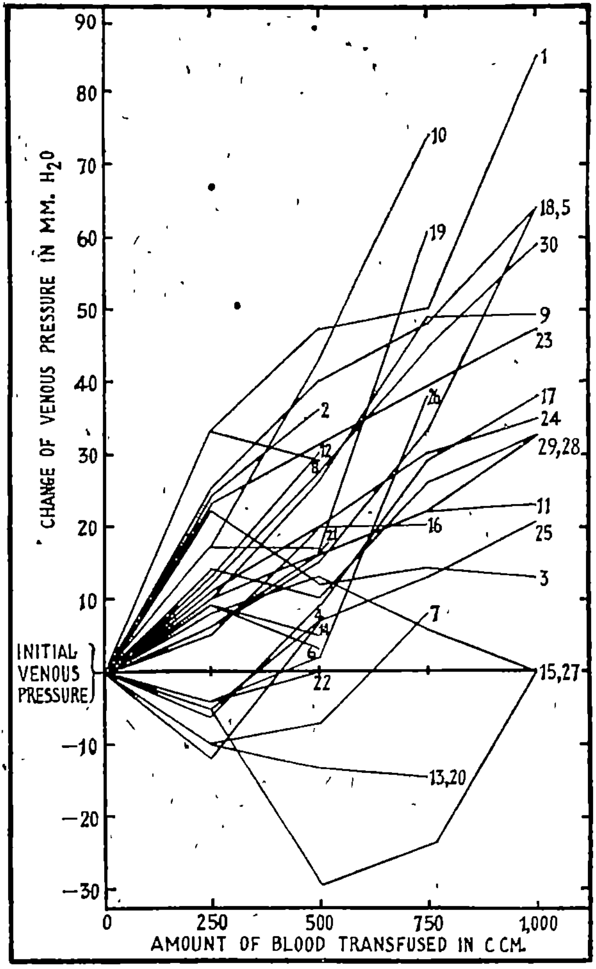
Transfusion

Observations were made on 30 unselected hospital patients (19 males, 11 females) suffering from secondary anaemias. In many cases the slight degree of anaemia would not have justified transfusion in the ordinary way. The chest measurements and approximate height and weight of all patients were recorded. They were allowed one pillow. This had no noticeable effect on the venous-pressure level. The preliminary rest period of 15 minutes was imposed and the venous pressure determined. The opposite arm was used for the transfusion, which was administered by gravity with the Medical Research Council giving-apparatus. Warmed compatible blood was given to all cases. The amounts varied from 500 c.cm. to 1,000 c.cm. In 4 cases the venous-pressure system blocked towards the end of the transfusion. The venous pressure was noted so far as was possible after every 50 c.cm. of blood had been transfused. In 5 cases the readings were continued at 5-minute intervals for 10 minutes after the end of transfusion and in a further 5 cases for 20 to 30 minutes. A rise of 20 mm. or less has been considered insignificant.

Venous Pressure and Amount Given.—Of the 30 patients, 19 showed a rise in venous pressure greater than 20 mm. H_2O, 10 no rise, and 1 a fall. In 13 cases the rise was between 20 and 50 mm. and in 6 cases between 50 and 85 mm. H_2O. In each of the 19 patients who showed a rise in venous pressure this increase was approximately proportional to the amount given, (see Graph).

Venous Pressure and Transfusion Rate.—14 cases were transfused at rates varying from 7 to 15 c.cm. a minute, the average being 12 c.cm.: 8 showed no change in venous pressure, 4 a rise between 20 and 50 mm., and 2 a rise between 50 and 80 mm. H_2O. 12 cases were transfused at rates of 16 to 30 c.cm. a minute, the average being 20 c.cm.: 3 showed no change in venous pressure, 6 a rise between 20 and 50 mm., and 3 a rise between 50 and 80 mm. H_2O. 4 cases were transfused at rates of 30 to 45 c.cm. a minute, the average being 37 c.cm. All 4 showed a rise: in 3 the increase was between 20 and 50 mm. and in 1 between 50 and 80 mm. H_2O. There was apparently no constant relation between the rate of transfusion and the rise of venous pressure, although proportionally more cases showed a rise at the faster rates. Signs and symptoms suggestive of vasodilatation were encountered in 3 cases. In one of these the interpretation of the signs was complicated by the onset of allergic manifestations.



Graph of the venous-pressure changes during the transfusion of blood to 30 unselected hospital patients.

Case 1.—Gastric ulcer, in a spinster aged 33, weight 7 st. 12 lb., height 5 ft. 4 in.; Hb 66%. The patient was given 540 c.cm. of blood at an average rate of 22 c.cm. a minute. The venous pressure at the end of transfusion showed a rise of 36 mm. H_2O. The blood pressure was 110/65 before and after transfusion. After 250 c.cm. had been given, flushing of the face and arms was observed and at the same time the patient complained of hotness of the face. This was followed successively by complaint of a throbbing sensation in the head and tingling of the lips. The flushing of the face and arms was present for several hours after the completion of transfusion. There was no rise in temperature.

Case 2.—A married woman aged 42; diagnosis—carcinoma of the rectum: weight 8 st. 4 lb., height 5 ft. 5 in.; Hb 78%. The patient was transfused with 950 c.cm. of blood at a rate of 16 c.cm. a minute. The venous pressure showed a rise of 64 mm. H_2O. The blood pressure before transfusion was 135/90 and immediately after transfusion 100/55. When 850 c.cm. had been given she complained of throbbing in the ears, followed in three minutes by palpitations, a feeling of fullness and hotness, and a generalized pumping sensation. After the onset of the symptoms, flushing of the face and both arms was noticed, and this lasted for 10 minutes after the completion of transfusion. There were no further signs or symptoms.

Case 3.—A married woman aged 61; a convalescent air-raid casualty: weight 7½ st., height 5 ft. 3 in.; Hb 66%. The patient was transfused with 990 c.cm. of blood at a rate of 15 c.cm. a minute. The venous-pressure rise was 38 mm. H_2O. After 450 c.cm. the patient complained of generalized hotness. After 600 c.cm. oedema of the right eyelid was observed, followed by flushing of the face. After a further 250 c.cm. the left eyelid also became oedematous, the flushing still being present. All signs had disappeared within 2 hours.

These 3 patients were transfused at rates varying from 15 to 22 c.cm. a minute (average 18 c.cm.). The rise in venous pressure varied from 36 to 64 mm. H_2O (average 46 mm.). In Cases 1 and 2 the venous pressure had risen significantly before the onset of signs or symptoms of vasodilatation, and remained steady in Case 1 and continued to rise in Case 2 until the end of transfusion. In Case 3 the venous pressure blocked just after the vasodilatation became evident.

The 10 cases in which recordings were continued after the end of transfusion showed a gradual fall in venous pressure, but in no case was there a return to the basal level within the next 10 to 30 minutes. In 26 of the patients blood-pressure readings were taken before and after transfusion. The changes after transfusion were variable and apparently not related to the frequent rise in venous pressure. Only minor variations in pulse rate were recorded, and these were inconstant.

Transfusion of Cases of Pulmonary Disease

Examination was made of 13 such cases—3 females, 10 males. The patients were allowed two flat pillows instead of one, as most of them found the supine position irksome. This position was maintained for at least 15 minutes before the vital capacity was recorded. The vital capacity was measured again after 500 c.cm. of blood had been given and at the end of transfusion (after 1,000 c.cm.). A Kendrick recording spirometer was used. In patients with rib resection the arm opposite the resected ribs was used for the venous-pressure estimation.

The transfusion rates given below are calculated from the actual time during which the 1,000 c.cm. of blood was being administered. However, it must be pointed out that after the first 500 c.cm. had been administered there was a time interval varying from 6 to 15 minutes (average 8 minutes), during which the vital capacity was being recorded and no blood transfused. The transfusion rates varied from 17 to 40 c.cm. a minute (average rate 23 c.cm.). The amount given was 800 to 1,000 c.cm. One case had 500 c.cm. only.

Vital Capacity.—With one exception every patient showed a decrease in vital capacity after receiving 1,000 c.cm. (1 case 500 c.cm.) of blood. The percentage reduction bore no constant relation to the original vital capacity. Clinically, 3 patients showed an increase of above 4 respirations a minute during the transfusion. One of these complained of a dry cough and another of dyspnoea during the night following the transfusion; the third patient, however, had no symptoms (Cases 12, 13, and 10, respectively; Table II). To exclude the possibility that the recumbent attitude was responsible for the reduction in vital capacity one normal subject and Case 10 of the pulmonary disease series assumed the posture for one hour without being transfused. There was no change in vital capacity in the normal subject, and only a 50 c.cm. drop in the other.

Table II.—*Effect of Transfusion of 1,000 c.cm. of Blood on Vital Capacity and Venous Pressure*

Case	Sex, Age, Diagnosis	Rate (c.cm. per min.)	Vital Capacity (c.cm.) Before Transfusion	Vital Capacity (c.cm.) Reduction after Transf.	Venous-pressure Change during Transf (mm. H_2O)	Transfusion Signs or Symptoms
1	M. 43 Empyema	33	2,450	150	+45	Headache
2	M. 44 Lung abscess	40	2,250	150	+77	Nil
3	M. 25 Pneumonectomy	20	1,900	350	+21	"
4	M. 52 Carc. bronchus	23	1,750	400	− 1	Nil. (Only 540 c.cm. blood given)
5	M. 59 Empyema	28	1,700	150	+81	Nil
6	M. 39 Pneumonectomy	22	1,450	150	+66	"
7	M. 50 Carc. bronchus	19	1,300	300	+33	"
8	F. 55 Empyema; rib resection	18	1,300	100	+ 6	Rigor 40 min. after transfusion
9	M. 21 Empyema; rib resection	20	1,250	200	−35	Urticaria, headache
10	M. 38 Pneumonectomy	25	1,250	300	+14	Urticaria
11	M. 21 Pneumonectomy	20	1,150	+50	−20	"
12	F. 45 Empyema; rib resection	17	1,100	300	− 5	Rigor 30 min. after transf. Dry cough during following night
13	F. 32 Pneumonectomy	18	750	200	− 5	Dyspnoea during following night

Venous Pressure.—Of the 13 cases of pulmonary disease 6 showed during transfusion a rise in venous pressure greater than 20 mm. H_2O, 2 a fall, and 5 no appreciable change. Again, in the 6 cases showing this rise the increase was approximately proportional to the amount given. None of these 13 patients developed signs or symptoms suggestive of vasodilatation.

Discussion

Normal Venous Pressure.—Lyons *et al.* (1938) consider that the normal venous pressure lies between 50 and 150 mm. H_2O. The same reference point being used, the cases in this investigation showed a similar range of venous pressure; though in one obese woman it was 167 mm. H_2O. According to Kroetz (1922) a raised venous pressure is common in obese subjects.

Venous Pressure During and After Venesection.—The constant and often striking fall in venous pressure during venesection (Table I) was, under the conditions of this investigation, unrelated to the arterial blood pressure or pulse rate. The subjects were a selected group in that all had previously undergone venesection. None had an established vasomotor collapse ("faint"), and so no record of the venous pressure during such an attack was obtained.

Venous Pressure During and After Blood Transfusion

Altschule and Gilligan (1938) in their study of the dynamics of the circulation used saline as a transfusion fluid and recorded the venous pressure at intervals. They found that it rose in the majority of cases transfused at rates above 20 c.cm. a minute, and this rise was proportional to the amount of fluid given. The venous pressure fell rapidly immediately after the end of these transfusions and reached the original level within 20 minutes. A rise in pulse pressure was commonly seen during transfusion. In all their cases receiving large-volume (1,000 to 1,500 c.cm.) transfusions a widespread flush was observed. The rise in venous pressure they interpret as being due to a failure of the peripheral vascular bed to dilate rapidly enough to accommodate the increased blood volume. Murphy (1941), who also used saline as a transfusion fluid, noted a rise in venous pressure during the first half-hour of transfusion. This was followed by a fall attributed by him to vasodilatation. There is no mention of this having been observed clinically, nor is it clear at what intervals the venous-pressure readings were recorded.

The present investigation, in which blood was used as a transfusion fluid and the venous pressure was recorded at frequent intervals, gave results similar to those of Altschule and Gilligan. As stated, 19 of the 30 cases had a rise of venous pressure greater than 20 mm. H_2O. This rise was approximately proportional to the amount of fluid given. The rate of transfusion played a less important part, but on the whole the faster rates showed greater venous-pressure rises. No correlation could be drawn between the venous-pressure rise and the age, sex, haemoglobin values, or chest measurements of the recipients.

In contrast to the findings of Altschule and Gilligan, the fall in venous pressure after the completion of the transfusion was slow. Moreover, in none of the 10 cases which were observed for the subsequent 10 to 30 minutes was there a decrease to the pre-transfusion level. This is probably due to the fact that blood was used as the transfusion fluid, and as a result the increase in blood volume was maintained for a much longer period than after the infusion of crystalloid solutions.

Symptoms and signs suggestive of vasodilatation were encountered in 2 patients who received 1,000 c.cm. of blood and 1 who received 500 c.cm. The rate of transfusion was greater than 15 c.cm. a minute and the rise of venous pressure greater than 30 mm. H_2O. However, other patients transfused at similar and faster rates and showing similar rises in venous pressure experienced no symptoms. All 3 patients were females of small stature. Although not beyond the limits of chance it seems possible that vasodilatation was more likely to occur in an individual with a small blood volume.

The cases with a venous-pressure rise either had no clinical evidence of peripheral vasodilatation or only developed signs and symptoms of this after the rise was already considerable. The peripheral vasodilatation was not accompanied by the fall in venous pressure described by Murphy.

Venous Pressure During the Transfusion of Cases of Pulmonary Disease

These 13 pulmonary cases, transfused at rates varying from 17 to 40 c.cm. a minute, were comparable to 16 of the first group of 30 cases, in which the rates varied from 16 to 45 c.cm. a minute. In the latter group 13 of the 16 cases showed a significant rise of venous pressure, whereas only 6 of the 13 patients with pulmonary disease showed an increase of similar extent. Venous-pressure rises were apparently less frequent in the group suffering from pulmonary disease, but the number of cases examined was too small to warrant drawing conclusions. In this group, too, the venous pressure increased with the amount given. There was a slight decrease during the interval when the intermediate vital capacity was being recorded.

Glaser and McMichael (1940) found a significant increase in vital capacity following venesection. They calculated lung volume in each instance and converted the changes into equivalent changes in blood volume. From these figures they deduced that 47% of the blood withdrawn came from the pulmonary vascular bed. Conversely, during a rapid transfusion one might expect that an appreciable proportion of the increased blood volume would be accommodated by the lungs. Altschule and Gilligan recorded the vital capacity in 4 of their cases, but they could find no change. In the present investigation vital-capacity changes were studied in patients with pulmonary disease. Such cases were chosen because in subjects with an already reduced vital capacity any further reduction due to the accommodation of the transfused blood in the lungs would be more readily appreciated. In point of fact, a reduction was seen in every case except one, but in most instances the reduction was such that it could account for only a small proportion of the transfused fluid.

If it is accepted that reduction of vital capacity is due to pulmonary congestion, then the question whether this is brought about by heart failure from overloading the circulation must be considered. In such cases a systemic venous-pressure rise would be expected. However, the only cases (3 and 7) that showed a well-marked reduction in vital capacity and an increase in venous pressure had no signs or symptoms suggestive of cardiac embarrassment. Furthermore, the 2 cases (12 and 13) that did develop respiratory signs and had the greatest percentage reduction in vital capacity had no increase in venous pressure; and the 4 cases (1, 2, 5, and 6) that had the greatest rise in venous pressure had only slight reduction in vital capacity. In this series there appears to be no direct relation between venous pressure and vital capacity. The changes in vital capacity therefore cannot be ascribed to cardiac failure. The accommodation of the blood is perhaps best explained by alteration in the capacity of various parts of the circulatory system. The signs and symptoms of peripheral vasodilatation seen indicate that the capacity of the subpapillary venous plexus was being increased. The rise in venous pressure and the reduction of vital capacity show that the larger veins and the lung capillary bed respectively were accommodating the extra fluid.

Since this paper was written Sharpey-Shafer and Wallace (1942) have published observations on the rapid transfusion mainly of serum and saline (300 c.cm. to 2,100 c.cm.) to subjects without cardiovascular disease. Their results indicate that the venous pressure is raised when there is considerable retention of injected fluid. Dilatation of peripheral vessels was noted, and an engorgement of the pulmonary vessels was shown by vital-capacity and radiographic records.

Conclusions

The venesection of normal subjects is accompanied by a fall in venous pressure. During the following 30 minutes there is a return towards the original venous pressure, although this level is not regained in this period.

During the transfusion of blood to unselected hospital patients there is in the majority of cases a rise of venous pressure which is approximately proportional to the amount given, and occurs more frequently at the faster rates. Signs and symptoms suggestive of peripheral vasodilatation were encountered in 3 of the 43 cases transfused. In these cases vasodilatation occurred after a rise in venous pressure and was not followed by a fall.

After transfusion, patients suffering from pulmonary disease showed signs of pulmonary congestion, as revealed by a reduction in vital capacity. This decrease was not related to the venous-pressure changes.

We should like to thank Dr. W. D. Nicol and the staffs of the medical and thoracic units of the Emergency Hospital and Mr. C. F. Swinton of the Mayday Hospital for access to cases. We are indebted to Dr. O. M. Solandt for help and encouragement.

A WATER-BORNE AND MILK-BORNE OUTBREAK OF PARATYPHOID B INFECTION IN WORCESTERSHIRE

POTENTIAL DANGERS OF RAW-WATER SUPPLIES

BY

S. CHALMERS PARRY, M.R.C.S., L.R.C.P., D.P.H.

Deputy County Medical Officer for Worcestershire

This small but none the less interesting paratyphoid B outbreak occurred from June to Aug., 1941, in one of the rural districts of Worcestershire where I was acting medical officer of health. It comprised a total of 17 primary and secondary cases, notified over a period of two months, and is of particular interest owing to the extreme rarity of epidemics of paratyphoid B fever recorded in which the organism has been recovered from water and which, in that respect, may be regarded as water-borne. Since the water that was implicated was not actually a drinking water, and since the milk supply was apparently contaminated secondarily from this water supply, I prefer to designate this outbreak milk-borne and water-borne rather than water-borne.

It will suffice to state that cases of paratyphoid B infection had recently occurred in adjacent areas and that the alleged source of infection had been traced to cream buns. While every patient in the present outbreak denied consumption of cream buns during the incubation period of their attack, an indirect and subtle connexion probably existed between these two epidemics.

History of Onset of Outbreak and Events Leading up to the Investigation of Farm

My suspicions were aroused on the discovery that there was a common milk supply to the first two cases of paratyphoid B reported (Table, Cases 1 and 2). On July 2, accompanied by Mr. Owen, county sanitary officer, I visited the farm which supplied milk to both these cases in order to ascertain, in particular, whether there was any sickness among the milk-handlers. The machine-milker, who had had some slight symptoms for a week or two, was on July 4 proved to have a mild attack of paratyphoid B fever (Case 5). Incidentally, his son, who had been admitted to hospital on June 26 with a history of three weeks' diarrhoea, was later diagnosed as a case of paratyphoid (Case 6). This important information proved the latter could not have derived his infection from milk contaminated by his father. A search for missed cases, carriers, and other sources of infection was made.

This bottling establishment also received milk from six local producers, and, while paratyphoid B organisms were absent in all milk samples submitted for examination, they were present in the *ram-water* used for dairying purposes. This ram-water was therefore the *missing link* we were seeking; for it was proved that the small son of the machine-milker contracted his infection from actually drinking the ram-water as it flowed in the gulley outside the dairy.

The machine-milker had ample opportunity of contracting paratyphoid from (1) his little son at home, (2) the tap-water in the cowshed,[1] and/or (3) drinking the raw milk. At the same time in the process of hand-stripping he had plenty of opportunities of contaminating the milk himself. The milk could also have been contaminated by the ram-water delivered from the cowshed tap. The milk was supplied from this farm in bottles to the private customers and in bulk to a big depot in the district.

Table showing Details of Cases

Case	Sex	Age	Paratyphoid B Widal Result "H"	Faeces	Urine	Clinical History	Remarks
1	F	6	+	–	+	"Cold" for 5 days. June 21: Fever, lassitude. 22nd: Diarrhoea. 29th: Rash, abdomen tumid, spleen +, liver +. "Typhoid state" for 2 weeks	Milk stated by parents always boiled previously. All family ate ice-cream twice a week
2	M	27	+	–	+	Indefinite. Jaundice since April 14. Stated illness began May 6. Fever June 13. Admitted hospital 20th. Epistaxis 28th. July 1: Tumidity, spleen +, liver +, "typhoid state" for one week. Jaundiced until about July 7	Date of onset very indefinite. At work until fever began. Very fond of raw milk
3	F	43	+	–	+	Poorly for about a week at work. June 24: Headache. 27th: Fever started; backache, headache, spleen +, liver +. No rash or tumidity	Canteen cook at depot. Handled uncooked food until evening June 27. Drank glass of raw milk daily
4	F	19	+	+	–	Sudden onset. Giddiness, pains in stomach and back. Frequent epistaxes June 21 to 28. July 1: Rash, tumidity, spleen +, liver +, constipation	Last worked at depot June 8. On holiday until July 1. No raw milk except in tea
5	M	26	+	–	–	Indefinite (1–2 weeks). Indigestion and backache. No diarrhoea. July 3: Headache; no rash or tumidity, spleen +, liver +	Machine-milker to bottling establishment. Father of Case 6. Fond of raw milk
6	M	2	+	–	–	Indefinite. Diarrhoea for 3 weeks. Admitted as suspected bronchopneumonia, diagnosed peritonitis until + Widal ("H" & "O") result July 5. Tumidity +, rash +, respirations rapid and shallow, with cough	Son of Case 5. History of having actually drunk ram-water. Drank raw milk
7	M	30	+	+	–	June 24: Epistaxis. 25th: Headache and lassitude. July 3: Diarrhoea and fever several days. 11th: Stiff neck, spleen +, liver +, rash +	No raw milk at depot except in tea; this had previously been added in urn
8	F	24	+	–	–	Sudden onset of intense headache, fever, and vomiting. July 6. Two rigors. 13th: Rash +	Stated she always boiled milk before drinking
9	M	1½	Nil	+	–	Diarrhoea since July 14. Fever since 18th. 22nd: Rash +, tumidity +	Admitted on + faeces (collected July 21, reported 23rd). Reputed to have last drunk raw milk from suspected source on June 18. Evidence inconclusive
10	F	18	+	+	–	July 22: Fever, headache, and aches in legs. 23rd: Rash +	Admitted as suspected case, being mother of Case 9. Blood culture – (collected July 23). Faeces + (received July 26). Leucocytes 11,550 (Aug. 7)
11	M	21	+	Nil	Nil	July 22: Headache, nausea, diarrhoea. 28th: Rash +, tumidity +, spleen +	Admitted on + blood culture (collected July 23, reported 28th). Died from haemorrhage Aug. 5. Uncle of Case 9
12	F	60	+	+	–	July 24: Sudden onset; headache, diarrhoea, vomiting. 25th: Collapsed with sudden acute abdominal pain and diarrhoea. 28th: Rash +, tumidity +	Blood culture – (collected July 25). Admitted on + faeces (collected 25th, reported 28th). Drank one glass of raw milk daily
13	F	21	+	+	–	Headache and pains in legs for 2 weeks; diarrhoea. July 26: Rash +. 28th: Epistaxis. 29th: Spleen +, liver +	No raw milk at depot except in tea. Last at work on July 21
14	M	55	+	+	–	Headache and febricula since July 22. Diarrhoea since 24th. Rash +. Aug. 1: Spleen +, liver +	Blood culture – (collected July 23). Grandfather of Case 9
15	F	10	+	+	–	Headache, fever, diarrhoea. Aug. 1: Spleen +, liver +	Blood culture – (collected July 23). Aunt of Case 9
16	F	11/12	+	+	–	Aug. 2: Fever for four days. 6th: Diarrhoea began. 8th: Fever, diarrhoea with mucus until 10th. Drowsy, tumidity +, green stools; rash +	All well-water boiled and all milk reported sterilized for child. Grandparents (living in same cottage) take milk from suspected farm; but child stated to drink milk from another source
17	M	58	+	–	–	Aug. 17: Sudden onset. Fever, diarrhoea, and vomiting 2 days; tumidity +. 28th: Admitted on relatively high paratyphoid B agglutinin titre	No raw milk at depot except in tea from urn. History T.A.B. inoculation (1917). Widal on Aug. 29 showed rising titre paratyphoid B agglutinins from 1/500 to 1/1,000 "H" in two days. [Typhoid agglutinin remained constant (1/125 "H")]

Events Leading to Investigation of Depot

Canteen Cook suffering from Paratyphoid.—On July 3 (i.e., the day before the Widal result of the machine-milker) Mr. Owen and I visited the depot to investigate a case of paratyphoid (Case 3) reported at one of the canteens. The patient was a cook who had been ill at work for about a week. It was evident that a salad-borne epidemic among the depot workers on that particular site was probable, and, in addition, a milk-borne epidemic among the farmer's private and depot customers was imminent.

Source of the Contaminated Ram-water.—One of the sources of the ram-water—two miles up-stream—was traced to the outfall of a sewage effluent from the depot.

Common Milk Supply.—Some of the paratyphoid B organisms, originally discharged from the depot in the sewage effluent, evidently completed their circular tour in the suspected milk supply, and a total of 5 cases of paratyphoid B fever (Cases 3, 4, 7, 13, 17) were notified among its employees. The fact that no raw milk was served over the counter at the canteens accounts for the negligible number of cases at the depot. The canteen cook (Case 3) was one of the few persons with access to raw milk. Milk was available only in tea; however, the actual procedure of making tea varied somewhat at the several canteens.

Course of Streams Contaminated by Sewage Effluents

A complete survey was made of farms and dwellings situated along the course of streams receiving effluents from the depot sites. We first explored the course of the brook from which the bottling establishment derived its ram-supply. This procedure entailed a visit to every farm in order to ascertain certain facts. The following five questions were asked (the answers apply only to the *bottling establishment*):

1. *Whether any Case of Sickness had Occurred Recently.*—One case of sickness—i.e., the machine-milker (Case 5), who was an immediate contact of Case 6—which may be regarded as definitely water-borne in origin. The type of sanitary accommodation at the milker's home is a privy, and the bucket contents are disposed of by burial in the garden.

2. *Access of Milch Cows to Brook containing Effluent, on Account of Possible Source of Contaminated Udders.*—At the

time of the outbreak all 12 milch cows had access to the contaminated brook water.

3. *Use, if any, made of Brook Water.*—The ram-water supply from the brook was used in particular for washing the machine-milker's hands before hand-stripping, and each udder and teats before milking, and for supplying the cooler and washing out the cowsheds. In addition it was used at the farmhouse for washing up the plates and dishes.

4. *Drainage therefrom—as any Contributing Source of Pollution to the Brook above the Ram-intake.*—The sanitary accommodation, used exclusively by the farm household, consists of a W.C. (supplied by ram-water) that discharges into a septic tank. The point of entry of the drainage from the farm is definitely below the point of intake of ram-water.

5. *Any Special Action taken.*—Immediate action taken was: (*a*) sterilization of the milk (from July 4 to 22); (*b*) removal of cows from access to brook; (*c*) use of well-water only; (*d*) cutting off the ram (following the bacteriological report on ram-water sample—July 12). Remote action taken was: (*a*) after a period of 18 days sterilization of the milk was no longer enforced; (*b*) after a period of 9 days the farmer was permitted to use chlorinated ram-water for washing out the empty cowsheds and for the cooler; (*c*) to continue employing well-water for cleansing the udders and teats and for washing the milker's hands and the bottles.

Commentary on Case Histories

Two cases (16 and 17) are worthy of special mention. Case 16 (see Table) gives an interesting history of combined Sonne dysentery and paratyphoid B infection. The source of infection remains a mystery. Case 17 gave a history of absence from the depot for several days during the incubation period, so the probability is that the source of infection was not derived from the depot; in any event, milk may definitely be ruled out. It is reasonable to suppose that the remaining 15 cases were associated in some way with spread of infection from the ram-water and/or the milker who contaminated the milk, or by secondary infection from another case (e.g., Cases 10, 11, 14, and 15 secondary to Case 9). Case 9, in my opinion, was attributable to raw milk drunk on July 2.

Whether the machine-milker (Case 5) was infected by ram-water from the cowshed tap or by direct contact with his son (Case 6) during his illness at home it is impossible to prove. As the onset of illness in Case 6 was estimated to be about June 5, it is safe to assume that the ram-water had been contaminated with paratyphoid B organisms some days previously and that the incubation period was exceptionally short (Warren, 1941).

Record of Laboratory Findings in Connexion with Cases

Isolation of Paratyphoid B Organisms by Culture from Faeces and Urine.—In studying the bacteriological results obtained from samples of faeces and urine submitted to the laboratory (see Table), it will be noted that there were 3 cases reported with urine + only; 9 cases with faeces + only; and 4 cases with faeces − and urine −. The first 3 cases recorded suffice to show how essential it is for specimens of *urine* to be sent to the laboratory; this is particularly important in the case of men, who micturate more frequently than women and who have correspondingly fewer facilities for washing their hands after the act. On the other hand, of course, women urinary carriers with unclean habits may be a greater menace to public health on account of their food-handling occupations.

Agglutination Tests.—With regard to the determination of the paratyphoid B Widal results, positive titres were obtained up to dilution 1/250 "H," except in two instances: Case 15 was admitted to hospital on obtaining an end-point of 1/125 "H," as the child was obviously a secondary case due to infection from Case 9. In Case 16 there was not sufficient blood to proceed further with the dilutions; but there is no doubt about the diagnosis, for, paratyphoid B bacilli were isolated from the faeces.

Blood Cultures.—Blood cultures were carried out on 4 patients in one family, the primary case of which—Case 9—was admitted to hospital on the recovery of paratyphoid B organisms from the stools. Only one positive paratyphoid B culture was obtained: this patient subsequently died.

Special Bacteriological Investigation

As a matter of exceptional interest, Mr. Monk submitted several cultures of paratyphoid B bacilli (through the medium of the Ministry of Health Regional Office) to Dr. A. Felix for phage typing. All these cultures, which were isolated during the outbreak, were tested against Vi phage preparations and found to react in an identical manner. The cultures were isolated from two patients, from the sewage effluent at the depot, and from the ram-water at the farm; and the result indicated that they all belonged to the same phage type.

Period of Survival of the Bacilli.—Using the dye method, it was estimated that the paratyphoid B organisms travelled through two miles of open stream for about 6 hours 7 minutes, and then through slightly less than 1/3 mile of piping for 34 minutes; the total distance from the sewage outfall at the depot to the tank at the bottling establishment taking 6¾ hours. These times and distances have been included in order to show the conditions through which *B. paratyphosus* B survived.

The Effluent Dilution Factor.—From observation alone it was evident that the effluent from the depot constituted a substantial fraction of the volume of the brook—even by the time it reached the point of ram-intake, which was situated two miles below the outfall. So I decided to estimate this dilution figure experimentally.

Determination of the Dilution Factor.—First of all it must be understood that the dilution of the effluent by streamlets within the precincts of the depot—over a distance of about 1/4 mile—may be regarded as negligible from a practical point of view. The degree of dilution undergone by the effluent at a point in the stream below the last tributary and above the position of the ram-intake was estimated. A dye was used for timing the speed of the stream. The true dilution factor was less than 1 in 4; or, putting the result still more dramatically, the effluent was diluted by slightly less than three times its volume of stream water along its course to the ram. Under weather conditions existing at the time of this experiment the dilution at the point of ram-intake was probably greater than just before the actual outbreak. I am indebted to Mr. W. Pembleton, the district sanitary inspector, for assistance in carrying out this investigation

Revelations and Recommendations

The epidemic illustrates two important facts:

1. *Potential Dangers of Hydraulic Ram-water Supplies under Wartime Conditions.*—Sewage effluents must find some outlet for discharge, and, in rural districts, brooks may be regarded as their natural course. The potential risk run by persons using hydraulic ram-water for domestic purposes must therefore be apparent, even though it may not be very significant. However, when an individual happens to be a food-handler, the health of a community may be endangered. Therefore, every farmer making use of a ram-water supply for cleansing the cowsheds and dairy must regard this water as potentially dangerous—for brook water is liable at any time to pollution. Ram-water really consists of a mixture of samples collected from a brook over a continuous period. Any sample taken direct from a contaminated brook may contain no harmful organisms, whereas a specimen of ram-water from the same brook is more likely to do so, for it is an accumulation of an infinite number of samples. This fact is pointed out as it is not generally realized that ram-water is even more unsafe than brook water *per se*. All users of ram-water should therefore take warning of the dangers of ram-supplies—especially under wartime conditions.

2. *The Importance of a Primary Planning Co-operation.*—During wartime large factories and works of every description are springing up in rural districts all over the country. They are built so rapidly and so secretly that the powers-that-be seldom consult the local authority on matters regarding the discharge of their sewage effluents. Co-operation between any particular branch of the Services concerned and the sanitary authority is essential, and, in order that the local knowledge of the latter shall be employed to the mutual advantage of both parties, it must start at an early stage in the planning of the sewage works and before the actual building has begun. This planning co-operation is of particular importance in rural districts, where there is danger of the effluents contaminating brooks used for dairying purposes; for the local sanitary

authority is the one and only body possessing that local knowledge of the district so essential before the plans are made. In the interest of general public health it is vitally important that powers over which the civilian authorities have no control should not discharge their sewage effluents into streams in dairying localities without this primary planning co-operation with the local sanitary authority.

Conclusions

The outbreak was due to a combination of factors, the chief predisposing causes being: (1) a hot spell and drought for the previous six weeks; (2) the recent incidence of paratyphoid "fever" in surrounding districts; (3) the inadequate dilution of the effluent from one of the sewage works at the depot; and (4) the comparative proximity of sewage outfall to ram-intake.

I am very grateful to Dr. Wyndham Parker, county medical officer, for his valued advice on all matters and for kind permission to publish this article. Thanks are due to the local sanitary staff and to Mr. R. W. T. Owen, county sanitary officer, for his indispensable support in carrying out the investigations. I am indebted to all the medical superintendents of isolation hospitals and the district medical officers of health who were good enough to supply me with clinical data, and to the local general practitioners for taking such prompt action to establish an early diagnosis in suspected cases. Grateful acknowledgment is made to Mr. H. E. Monk, county analyst and bacteriologist, and to his staff, for their enthusiastic co-operation. I also wish to express my appreciation of Prof. J. F. D. Shrewsbury's kindly help and criticism.

FATAL PHOSPHORUS POISONING FROM AN EXPLOSIVE BULLET

BY

A. J. BLAXLAND, M.S., F.R.C.S.
Senior Surgeon, Norfolk and Norwich Hospital

It is well recognized that certain types of incendiary bomb may cause local damage to skin or a wound from phosphorus contained in them, but, so far as I am aware, there is no appreciable risk of poisoning from absorption in these cases. The proportion of phosphorus present is, I understand, quite low—only about 4%. The risk of absorbing a lethal amount of phosphorus is apparently very much greater in penetrating wounds caused by a certain new type of explosive bullet. In the case recorded below there seems to be no reasonable doubt that death was due to phosphorus. Similar cases may have occurred without recognition of the cause of death, and I feel that it is important that the medical profession should be on the alert for them.

Case Report

A Canadian airman navigator aged 24 was wounded in the early hours of Sept. 14 in action over enemy territory. His aeroplane landed at a near-by aerodrome, where he was given morphine and his wound was dressed with sulphanilamide. He arrived at the Norfolk and Norwich Hospital at 9 a.m. There was a ragged entrance wound on the outer aspect of the left thigh, 2 in. long. His abdomen was rigid and tender, with dullness over the lower half. He was suffering from extreme shock. Pulse 144; B.P. 65/0. Three pints of serum were given intravenously and his B.P. gradually rose to 120/60. A radiograph showed a metallic foreign body in the centre of the abdomen, a punch fracture of the wing of the left ilium, and also some small metallic fragments in the thigh above the entrance wound and below the fracture.

Operation was begun at 11.30 a.m. The abdomen was opened and over 2 pints of blood mopped up. A ragged portion of a distorted bullet was found embedded in the upper part of the mesentery. This was extracted, and large torn branches of the superior mesenteric vessels were ligated. A transverse tear in a loop of jejunum was sutured and invaginated. There were no other intra-abdominal injuries, but some scattered fragments of bone were present in the subperitoneal layer of the abdominal wall on the left side. The abdominal incision was closed without drainage. The entrance wound in the left thigh was then enlarged up to the site of the penetrating fracture in the ilium, the edges of the skin and damaged muscle were excised, and some loose debris wiped away with gauze. While doing this it was noticed with astonishment by myself and my assistant that the wound emitted a visible vapour. This vapour was then found to possess the smell characteristic of phosphorus. The wound was impregnated with sulphanilamide powder and lightly packed with gauze. My first impression on smelling the vapour was that it was due to a tracer bullet, but examination shortly afterwards in a dark room failed to demonstrate any phosphorescence. During the operation a blood transfusion of the same group (O) as that of the patient was started, and it was continued until he had received 3 pints. The blood pressure at the end of the operation was only 84/40, but by 8 p.m. it had risen to 134/60.

The following day the patient's general condition was fair, with some vomiting. On the 16th he had improved, and his general condition was satisfactory: no vomiting; abdomen soft; no gas in the wound or spread of infection. On the 17th he was not so well, and was slightly restless. Abdomen soft; no vomiting. The wound in the thigh was unhealthy. On the 18th he was obviously deteriorating and very ill—restless and semi-comatose. There was a lemon tint in the skin. A blood count showed 3,000,000 red cells with haemoglobin only 38%. A pint of blood was given. No urine had been passed for 24 hours, and a catheter withdrew less than 2 oz. The blood transfusion was followed by a continuous drip of saline and dextrose. The abdominal wound broke down and was strapped.

On the 19th the patient was comatose. In spite of the many pints of fluid given intravenously the anuria continued, not more than 1¼ oz. of urine being withdrawn by catheter. Examination of the blood showed that the haemoglobin had risen to 58%. The blood urea was 453 mg. per 100 c.cm. His pulse remained comparatively slow—92 to 100 during the day—and was of quite good volume. He died at 1.50 a.m. on the 20th—that is, 6 days after being wounded.

Report on the Necropsy, by Dr. G. P. C. Claridge, Hon. Pathologist to the Norfolk and Norwich Hospital

At the post-mortem examination a gaping wound was found in the left thigh from which there was a track up into the tissues of the left flank passing through the iliac bone. The edges of this wound showed some necrosis, but not more than one often sees in these war wounds. The peritoneal cavity was clean and the stitching of the intestine sound. The liver was not enlarged, but on section had a homogeneous appearance and the cut surface was of a dull yellow colour. Apart from some slight swelling of the kidneys there was nothing of note in the other abdominal and thoracic organs.

Microscopical sections of the liver show extensive necrosis with fatty degeneration; the lobules cannot be identified, while the liver cells, which can still be recognized as cells, have a hazy outline with absent or shadowy nuclei which take the eosin stain, and a granular and highly vacuolated cytoplasm. Sections of the kidneys show the changes of catarrhal nephritis, the cells of the convoluted tubules being enlarged, granular, and in many cases necrotic. These changes in the kidneys are in themselves insufficient to account for the anuria. The gross destructive lesion of the liver is typical of acute phosphorus poisoning.

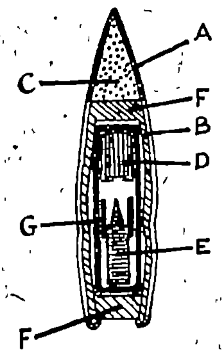
Comments

The rapid deterioration in the patient's condition after making good progress for the first three days, with the local condition in the abdomen and thigh satisfactory, was most puzzling at the time. The anuria and uraemia led me to surmise that it might be caused by some incompatibility of blood, although there were no symptoms to suggest that during the transfusions. The microscopical appearance of the kidneys makes it unlikely that incompatibility had any part in the fatal result.

The condition of the liver is not readily explained by anything other than phosphorus poisoning. If that explanation is correct, the important point arises as to what could be done to eradicate or counteract the poison in similar cases in the future. A more extensive excision of the damaged area than usual is indicated, and the application of a chemical antidote. I am ignorant as to whether copper sulphate would be of value. I believe that its use in the treatment of phosphorus burns of the skin is mainly as a colour index of the exact position of the phosphorus, and that the phosphorus has to be scraped off and further copper sulphate applied, to discover if there is any more to remove.

Apart from the evidence of necrosis of the liver and the presence of the vapour in the wound, with its distinctive smell, I have recently collected further and more convincing proof that this case was one of phosphorus poisoning. Lieut. K. M. Wheeler, R.E., has, with much kindness, great enthusiasm, and some risk to himself, done some research work for me. He has matched the distorted remains of the bullet with some identical bullets from a batch found on a wrecked German plane. His investigation proved it to be an explosive bullet—containing a charge of high explosive and also 3¼ gr. of phosphorus—which is double the minimum fatal dose recorded (Sydney Smith, *Forensic Medicine*, 4th ed., p. 472). A replica of the striker of the detonator in the bullet was found in the portion of bullet removed from the patient; and also traces of phosphorus were detected on this portion by chemical tests. The radiographic evidence of minute portions of metal in the thigh and the ragged large entrance wound suggest that the bullet exploded in the tissues of the thigh, probably on striking the iliac bone, thus releasing and scattering the concentrated phosphorus.

A DESCRIPTION OF THE BULLET, BY LIEUT. K. M. WHEELER, R.E. It is a 0.312 Mauser pattern bullet. Its total weight is about 10.6 g. The outer case of the bullet is in two layers, except the nose—the outer layer of hardened iron with copper plating (A), the inner layer of lead (B); the whole of which encloses, in the nose of the bullet, a concentration of phosphorus (C); and in the main body a brass sleeve containing a detonator (D), of high explosive, actuated by a striker (E). F, F are lead plugs, and G is a safety device. The total quantity of phosphorus is the equivalent of 3.254 gr., most of which is in the nose, although some seems to have crept up between the inner and outer skins of the casing.



I wish to acknowledge my indebtedness to Lieut. Wheeler, whose research work largely solved the mystery of the death; to Dr. Claridge for his help and advice; to Dr. John Williams of Messrs. Reckitt and Colman Ltd., who supplied the chemical data; and to my house-surgeon, Mr. W. P. Hirsch, who assisted me at the operation and was responsible for the after-treatment and clinical notes.

Medical Memoranda

Urticaria with Pigmentation as a Sequel of Scabies

As an unusual sequel of scabies the following case may be of interest.

CASE RECORD

In February of this year an airman aged 20 complained of paroxysmal irritation, localized to small pigmented papulo-macules, which when rubbed became elevated as in urticaria pigmentosa. His history was that in July, 1941, he was treated with sulphur ointment for scabies. As the irritation did not disappear he then received treatment with benzyl benzoate on four different occasions up to September, 1941. Late in August, 1941, he noticed that the irritation was confined to a small, flat, brownish pigmented lesion on the site of an old scabietic burrow on the left axillary fold. A week or so later he noticed similar pigmented lesions on the abdomen, left upper arm, and trunk; all were about the size of a silver threepenny-piece. The irritation was paroxysmal, in bouts, nocturnal and diurnal, lasting some minutes and confined to the lesions, which, when rubbed, became definitely more prominent and raised above the surface. This swelling would last a few minutes and then decrease, with a consequent extinction of the irritation. The majority of the lesions were on the abdomen. There were also a number of small dark-brown pigmented non-hairy moles on the abdomen and arms which had been present since birth.

The patient was above average intelligence and there was no evidence of a psychogenic factor. He was medium in colour of complexion and hair, and stated that he sunburned slowly. As a child he had had "heat spots" occasionally, after eating porridge. There was no dermographism.

During the four months under observation there has been some decrease in the pigmentation. The urticarial response and the paroxysmal irritation are now absent. Biopsy showed a consistent intracellular increase in the melanin throughout the lesion in the lowest two cell layers at the base of the stratum malpighii; melanoblasts were normal in distribution and pigment content. The epidermis and dermis were normal in thickness. The hair follicles, sweat glands, and sebaceous glands were all normal, but around some sweat glands, and around all capillaries, superficial and deep, was a definite round-cell infiltration; no eosinophils were seen. The cells lining the capillaries gave the impression of slight swelling, but all were empty of blood.

COMMENT

The absence of mast cells in the biopsy excludes urticaria pigmentosa. One would suggest that the lesions represent a peculiar sensitization response to local results of scabietic infestation.

I wish to thank Dr. J. T. Ingram of Leeds for his advice.

GEOFFREY A. HODGSON, D.M.,
Major, R.A.M.C., Dermatologist.

Reviews

DRUGS OF ADDICTION

National Research Council. Report of Committee on Drug Addiction 1929-1941, and Collected Reprints 1930-1941. (No price given.) Washington, D.C.

This huge volume of 1,581 pages contains, besides the report of the committee, reprints of numerous papers embodying the results of researches made on the chemical, pharmacological, and clinical aspects of addiction during 11¼ years. To read it through would be, as Sir Thomas Browne might say, "a work not to be performed on one leg," though only a captious critic would complain that "more authors are quoted in one work than are needed in a whole world." As a book of reference it will be found invaluable, and it is indispensable as an exhaustive record of the very important researches on addiction which have been carried out in the U.S.A. during more than a decade. The hope expressed that the foundations thus laid "may be of value not only to contemporary research but to posterity" can fairly be grouped among those hopes which are "sure and certain."

It is, of course, impossible to do adequate justice to a book so rich in content within the exiguous space at our disposal. While the chemical and pharmacological studies will deeply absorb specialists in those branches, it is to the clinical papers that the practising physician will chiefly turn. As regards the two former aspects, it will perhaps suffice to say that, while the ultimate goal is still far off, proof has been afforded of the possibility of so manipulating the morphine molecule as to produce substances which exhibit, in a certain degree, less of the undesirable and more of the desirable effects of morphine. Especial mention may be made of two morphine derivatives, desmorphine and metopon, which have been found to possess greater analgesic powers than morphine and, as regards the latter, less liability to addiction. Hopeful as such results seem to be, yet the conclusion is regretfully reached that while one of the two (metopon*) is an excellent analgesic for chronic pain and has promise of being a real addition to our armamentarium—especially in the field of terminal cancer—yet morphine, in spite of its disadvantages, still holds its position as the most satisfactory phenanthrene derivative in the majority of cases when used with due caution. A promising field of research has also been opened up among the amino-alcohols, for it has been found that the phenanthrene nucleus is not essential for analgesia. It was found also that the most convenient method for assessing the addiction factor in new compounds was observation of their capacity or incapacity to maintain pre-established physical dependence upon morphine.

Coming to the more clinical aspects of addiction, Treadway estimates the proportion of addicts to the general population in the U.S.A. as about 1 per 1,000. Himmelsbach and Small, in another paper, usefully clear the ground by demonstrating the uselessness of certain remedies much lauded by some. Thus, e.g., "rossium," the barbiturates, and insulin were found to be without any real beneficial effect upon the abstinence syndrome. Kolb, in another paper, gives reasons for his belief that belladonna treatments, pilocarpine, the endocrines, and immunity treatments are of little or no value, and, indeed, states that all treatments based upon theories of addiction mechanism have been failures, since that mechanism still remains obscure. All may not go with him quite so far, but his arguments deserve careful study. The chief positive contributions to treatment are contained in the papers by Kolb and Ossenport and Kolb and Himmelsbach which describe the method used at Lexington Hospital. The drug is first withdrawn, then physical and mental rehabilitation is undertaken within the institution, and, lastly, the patient is adjusted to outside conditions in preparation for his return to society. Intensive psychotherapy is given only to selected patients, but occupational therapy, recreation, and a grade of custody or supervision loom large. Drugs play a minor part. As regards withdrawal, the plan recommended for the generality of cases is a rapid but not abrupt withdrawal, helped out sometimes by a few doses of codeine for two or three days. The authors deprecate abrupt withdrawal in addicts with strong habits as cruel, dangerous, and unnecessary.

---

* Metopon (methyldihydromorphinone) is, however, not yet available commercially.

An extremely valuable book would, however, be even more valuable if someone could be found to undertake the prodigious task of compiling an adequate index. Perhaps such an index could be issued as a supplement to the volume? It would be an inventory of a real treasure house.

VAGINAL HYSTERECTOMY

Vaginal Hysterectomy. By James William Kennedy, M.D., F.A.C.S., and Archibald Donald Campbell, M.D., F.R.C.S.(C.), F.R.C.O.G., F.A.C.S. (Pp. 495; fully illustrated. $10.00 or 60s.) Philadelphia: F. A. Davis Company; London: H. K. Lewis. 1942.

It is quite customary nowadays for medical books to be written by two authors, but it is unusual for two recognized experts in different countries to combine to produce a monograph on such a special subject as vaginal hysterectomy. This, however, has been done by Kennedy of Philadelphia and Campbell of Montreal, and may be considered to be a sign of the times illustrating the reciprocal value of the lease-and-lend policy. The appropriation of 495 pages for such a monograph might seem to be superfluous, but this is in nowise the case. The operation of vaginal hysterectomy is one that is comparatively seldom done in this country at the present time, though it had many advocates in the past; it is, however, much more frequently performed in Canada and the United States and on the Continent: it is, therefore, most opportune that this monograph should be published to allow British gynaecologists to revise their ideas as to the suitability of the operation and to be able to appreciate the full details of the operational technique as practised by these two experts.

The book begins with an interesting historical account of the operation, interspersed and enlivened by many interesting anecdotes; this is followed by Kennedy's account of the clamp method of vaginal hysterectomy which he and his predecessor, Price, have practised for sixty years; he goes into the indications, operative details, post-operative treatment, and complications very fully, and, though all the indications would not meet with universal approval, many warrant very careful consideration by British gynaecologists. His mortality rate of under 1% in 4,000 cases is in itself sufficient reason for a more extended practice of the operation. We note that he has never encountered a death from embolism following this operation. This would also seem to refute condemnatory statements regarding the operation, which Kennedy states are made by those not accustomed to its performance, but he lays himself open to a similar criticism for his remarks on the Manchester operation for prolapse. Vaginal hysterectomy would seem to be of especial value in cases of carcinoma corporis, pre-cancerous cervix associated with menorrhagia, and procidentia. Campbell gives a very full account of the anatomy of the pelvic floor, especially with regard to the aetiology of prolapse, which he discusses thoroughly; he then goes on to describe in detail his admirable operation of vaginal hysterectomy with sutures in association with pelvic floor repair for prolapse. From the point of view of one who has seen Campbell at work this is an operation which is well worth detailed study by all gynaecologists who are unacquainted with it.

The beautiful binding, the luxurious paper, and the excellent printing give the book a pre-war appearance which is most refreshing and stimulating, but its chief attraction is the beautiful and detailed illustrations, of which there are 120: these for the most part are whole plate and are so exquisitely drawn as to make the steps of the operative technique easily understandable, for each step is most adequately depicted.

It is essentially a book for the practising gynaecologist, who will be well repaid by its purchase.

LOCAL GOVERNMENT

The Municipal Year Book. (Pp. 1,450. 40s.) London: The Municipal Journal Ltd. 1942.

This encyclopaedia of local government administration makes its appearance again, apparently undiminished in bulk, and as informative as ever. It is not as rich in statistics as were pre-war issues, but, then, the value of statistics is mainly for comparative purposes, and the war has made comparisons useless.

To make up for the loss of some sections, others having a close bearing upon wartime administration have been introduced, including war damage, planning, building, and reconstruction. If the reader wishes to look up recent legislation affecting local government, or defence regulations, or law cases, or important official documents, this volume will prove an unfailing source of reference. Similarly if anyone is curious to know the constitution and personnel of urban and rural councils from Orkney to the Isles of Scilly, or particulars of corporation properties, housing schemes, rates, or indebtedness of boroughs from Lowestoft on the east to Aberystwyth on the west, this work is as ready with its information as a cash register.

In the section devoted to public health services there appears a useful directory of orthopaedic centres and fracture departments and clinics. There are eight orthopaedic centres in the London sectors and ten in other regions. The fracture departments "A," which are suitable for long-stay cases, number 55; the departments "B," which are for ambulatory and short-stay cases, number just 200; and the fracture clinics "C," for out-patient treatment, just over 100. An outstanding feature is the number of "B" departments in Yorkshire and Lancashire—more than two dozen in each county. Another feature of this section is a list of the institutions which have been "appropriated" under the Local Government Act, 1929. Those appropriated as general hospitals number 32 in London, 15 in the neighbouring counties of Middlesex, Kent, and Surrey, but only 23 in other county areas of England and Wales, and 54 in the county boroughs.

This work of reference, while severely matter-of-fact, does manage to convey the fascination of local government, with its many fingers reaching down into the life of the community, more intimate and in some ways more interesting than national politics. It also illustrates the vast amount of public service, largely unpaid and unacknowledged, which local government is able to enlist, and the valiant part it is taking in the organization of the country for war and for the tasks of peace that will come after it. We hope the future historian of these times will not be so occupied with Westminster and Downing Street as to forget the hundreds of civic centres and town halls.

Notes on Books

The *Medical Progress Annual,* Vol. III, 1942 (Baillière, Tindall and Cox; 27s. 6d.) is a reprint of 52 articles which appeared in the *New England Journal of Medicine* during the successive weeks of 1941. The standard of editorship and production of the book is high. The articles range over the whole field of the progress of medicine in its widest sense, and, being by chosen authorities, they are almost uniformly excellent. Taken in a dosage of one a week they might well have been stimulating, but it must be confessed that they make heavy reading when combined in one volume. Readers who are not under the spell of local patriotism will question the wisdom of a publication of this kind. Medical progress is already reported in medical annuals, yearbooks, annual reviews, and monographs, at a length which is hardly justified by the pace of significant discovery. Many British readers will feel that, if any addition is necessary, a system of abstracting, such as they have learnt to appreciate in the *Bulletin of War Medicine,* is a better way of classifying advances and giving prompt and wide circulation to what is important.

Preparations and Appliances

A SYNTHETIC MORPHINE SUBSTITUTE

Roche Products Ltd. recommend for trial a synthetic morphine substitute called pethidine. It is closely allied to morphine in composition, and is issued in 25-mg. tablets and 50-mg. ampoules. It may therefore be administered intravenously (1 to 2 c.cm. over 3 minutes) for the immediate relief of pain, as well as orally (25 to 75 mg. two or three times a day). It is claimed that pethidine will relieve pain without impairing consciousness or co-ordination, and that it is valuable in renal or biliary colic because of its anti-spasmodic activity. It is comparatively free from toxic effects, though medullary depression and other side reactions may occur on intravenous injection; nevertheless it would seem to have many of the properties of morphine without certain of its disadvantages.

INFANT AND MATERNAL MORTALITY

A number of thorough investigations have been made in recent years into the causes of death of mothers in childbirth and of infants before the end of the first month. It is common knowledge that neonatal mortality has not shared in the general fall in the infant mortality rate and that the maternal death rate—at least until the introduction of the sulphonamides—has remained for many years at a disturbingly high level. Some of the reports based on these inquiries lie on dusty shelves, but others were used as a framework for legislation. The latter tended on the whole to emphasize the technical aspects of the subject, leaving the layman with a vague, comfortable feeling that all would be well if we had better ante-natal services and more competent midwifery. The most recent report[1] blows a cold east wind on these delicate illusions by taking into account the wider biological and social implications of child-bearing. In this investigation, which comes from the Department of Physiology of Durham University, Mrs. C. M. Burns reports the results of an exhaustive study of the records of health visitors in the administrative county for the years 1930-7. Its main object, as the author puts it, is to consider the relation of the age of a woman to her fitness for motherhood, such fitness being measured by the chances of survival of mother and child; this necessarily implies a study of the number of children born and the rate of breeding. The subject-matter falls roughly into two parts, the first dealing with the history of some 17,000 children born in the year 1930, and the second with the maternal deaths which occurred during the whole period under review. The age and parity of the mother were known in over 15,000 cases, and from these records it has been possible to draw conclusions which are not made less positive by cautious insertion of the phrase "it would seem to be."

In a recent work Julian Huxley says: "If we wish to work towards a purpose for the future of man we must formulate that purpose ourselves. Purposes in life are made, not found." The essay which Mrs. Burns has written is an illustration of this truth, and it is rightly described as "a study in human responsibility." Many of her conclusions lay a new stress on what is already accepted, but they are set in the form of a challenge to action. We know, for example, that the lowest infant death rates are found in first, second, and third children born to mothers between 20 and 35, and fourth and fifth children to mothers between 35 and 40; and that the infant death rate is abnormally high among *first* children born to mothers under 20 and over 30. The age of a mother at the birth of her first child is therefore a factor of prime importance in a forward social policy, and it is evident that this biological consideration is relatively unaffected by improved medical, nursing, and social services. The only remedy is to encourage marriage and the foundation of a family at the most favourable age. The second major influence on the preservation of infant life is the spacing of the family. It is abundantly clear from the figures presented that a rapid succession of pregnancies means a high death rate, and once again biological causes predominate, and we cannot expect to secure great advances without taking these into consideration. As the author says: "It is a mistake to lose sight of the woman in the mother. Many women are more in need of ante-conceptional than ante-natal advice, and any service that proposes to care for maternity must not relinquish responsibility at the end of ten days after childbirth, but must be responsible for the woman's health throughout the entire reproductive period."

The Durham investigation brings out a number of other facts of great interest, many of which are applicable to the country as a whole. It shows that, contrary to the general belief, first children, once they survive the perils of birth, are just as healthy as the rest. The late children of large families, however, have a high death rate at all stages—infancy, childhood, and adolescence. The relation of infant mortality to social conditions is also discussed, but the material is not well adapted for firm conclusions. As might be expected, there is a relatively high death rate in overcrowded homes, but the figures suggest that the size of the family rather than the overcrowding as such is the harmful factor. First children living under the same overcrowded conditions as seventh children had the death rate of their own birth rank, not the higher figure of the late child in a large family. It is pointed out, however, that the inquiry applies to a county area and not to the slum conditions of a great city. When we come to the discussion of maternal deaths the same general conclusions hold good. The death rate among women bearing their first child after the age of 30 was four times that of primiparae between 20 and 25. Where marriage or the first childbirth is postponed till after 30, not only is the first birth relatively dangerous but all subsequent births are associated with a maternal death rate relatively high for that stage of the family. "This in part explains the absence of improvement in the figures for maternal death rates in the more fortunate classes, who on the whole marry later than the working classes." Unfortunately, late marriage is no longer the monopoly of the well-to-do; it is spreading among the capable and the prudent in all trades and professions which demand a period of preliminary apprenticeship. These groups suffer a double disadvantage—late marriage and small families—and the author suggests that these groups are faced with extinction.

Two broad considerations of policy emerge from this inquiry: first, that not enough stress has been laid on the biological factors concerned in maternal and infant mortality. What are we going to do in order to secure that marriage and the foundation of a family take place at the best biological ages (i.e., 20–25)?; and, How are we to achieve better spacing of families—which counts so much towards the health and efficiency of the mother? The second consideration is still more fundamental, but it depends to some extent upon the first: How are we to prevent the breeding of the unfit? Mrs. Burns says that "in this country it is already broadly true that only those who are unable to look after themselves are increasing their numbers," and quotes (with apparent approval) a statement of the Chief Medical Officer to the Ministry of Health (1935): "We must not overlook the fact that, if the nation saves infant life on this scale, it must not be surprised if many weakly and perhaps even defective children are saved, which tend to increase the number of unfit." Elsewhere Mrs. Burns speaks of infant death as a process of weeding out the unfit, as though the survivors must inevitably be healthy. But is there evidence to suggest that the appalling death rates of a century ago were merely the weeding of a garden? We know very little of morbidity figures except in relation to infectious disease, but all the keenest observation of the period indicates that the quantity of ill-health was then greater both absolutely and relatively to the number of deaths. Records of death are a small and somewhat biased sample of the total volume of sickness, and one may venture to doubt whether, as stated in the concluding remarks by Prof. David Burns, the misfits of civilization, who at present form about 10% of our population, will form 30% of the next generation. We have only just begun to try the effect of education and social welfare on the bulk of our people.

THE ANTI-PERNICIOUS-ANAEMIA FACTOR

The therapeutic triumph over pernicious anaemia must remain incomplete until it is found possible to produce this disease experimentally in animals. Only in this way will it be possible to standardize efficiently preparations used in treatment. Perhaps of more fundamental importance is a closer understanding of the deranged physiology of hyperchromic anaemias. The initial problem, still unsolved, is to determine the location of the intrinsic haemopoietic factor in the stomach. Meulengracht's investigation[1] indicated that preparations made from the pig's pylorus were much more potent in the treatment of pernicious anaemia than those derived from the cardia, while extracts of the fundus were completely inactive. Total gastrectomy, however, failed to produce a pernicious-anaemia syndrome in the pig, dog, or monkey, even after the subsequent institution of defective diets, the administration of poisons such as carbon tetrachloride, or infestation with *Bothriocephalus latus*.[2] In this series of experiments it was found that hypochromic anaemia developed much less frequently when the stomach, although isolated from the rest of the alimentary tract, was left in the body, a fact which favours the hypothesis[3] that the stomach may have some hormonal function in haemopoiesis. The failure to produce a condition of pernicious anaemia by gastrectomy naturally led to the consideration of the possibility that some region producing the anti-anaemic factor was still functioning in the body. Attention was then focused on that part of the duodenum containing Brunner's glands, which resemble the glands in the pylorus. Sharp and his colleagues,[4] indeed, found that the dried duodenum of the hog had a therapeutic effect on pernicious anaemia similar to that of preparations of dried stomach. This observation was confirmed by Meulengracht.[5]

Petri and his colleagues[6] [7] have studied this aspect of the problem of the experimental production of pernicious anaemia by means of selective resection of various regions of stomach and duodenum. Three types of operation are reported: (1) total gastrectomy with resection of the Brunner-gland area of the duodenum, (2) resection of pylorus and Brunner-gland area, and (3) resection of pylorus and entire duodenum. In none of the animals, pups and adult dogs, was the picture of pernicious anaemia produced, though in all there appeared symptoms of pellagra, relatively mild in the adult animals but much more severe and at times rapidly fatal in pups. If Castle's view as to pathogenesis is accepted, the attempt to produce pernicious anaemia failed because the experimental procedure did not completely destroy the ability to form the intrinsic factor. Uotila,[8] indeed, has already shown that preparations derived from the small and large intestine, but especially the ileum, of swine did possess some anti-pernicious-anaemia factor, though they were not so potent as those made from pylorus or upper duodenum. Accordingly Petri and his co-workers tried to produce pernicious anaemia by resection of the pylorus, the Brunner-gland area, and the distal two-thirds of the small intestine. This resulted in the appearance of a macrocytic hyperchromic anaemia, with pathological changes in the central nervous system, but there was no marrow hyperplasia and recovery was spontaneous. Accordingly, so far as experimental pernicious anaemia is concerned, another failure has to be recorded, but the morbid condition brought about may be included in that group of diseases such as tropical macrocytic anaemia, *Bothriocephalus latus* infestation, and sprue, and indeed may be identical with the pellagrous syndrome associated with hyperchromic macrocytic anaemia. It is possible that the inability to induce pernicious anaemia in dogs is due to the choice of unsuitable combinations of resections or to the need for associating dietary deficiency, such as B-hypovitaminosis, with gastro-intestinal interference.

It is well known that the haemopoietic factor, presumably manufactured in some region or regions of the alimentary tract, is stored in the liver. The anti-pernicious-anaemia potency of the liver of any animal is therefore an indication of the amount of haemopoietic factor formed and absorbed. Petri and his colleagues[9] have utilized this in devising a series of investigations wherein was estimated the therapeutic efficacy on pernicious-anaemia patients of livers from animals that had survived for at least 166 days after various sections of the alimentary tract had been removed. This ensured the disappearance from the liver of any haemopoietic factor previously absorbed from the resected portions of the stomach and intestine. In agreement with earlier workers, Petri found that after total gastrectomy swine liver completely lost its anti-anaemic principle, but it was also found that resection of the fundus had the same effect. This somewhat startling result raises further problems as to the formation and absorption of the anti-anaemic factor. The fundus has no therapeutic effect in pernicious anaemia, but it must play an important part in the synthesis or absorption of anti-anaemic factor in other regions of the alimentary tract. This fits in with the fact that in patients with pernicious anaemia the fundus shows the most pronounced histological changes. It is perhaps foolish to speculate on the nature of the fundus action, but it is worth while mentioning preliminary experiments by Petri indicating that administration of nicotinic acid for a period of six months restored the anti-anaemic potency of the liver in a hog with the fundus resected but not in one on which a total gastrectomy had been performed. This favours Castle's view that the intestinal content of anti-anaemic factor is not the result of local synthesis but is due to absorption of pre-formed substance. There can be little doubt that if these results are confirmed and extended a new field of work is opened for physiologist and clinician.

Although the experimental production of pernicious anaemia still eludes us, some interesting information has been gathered on the pathogenesis of experimental endogenous pellagra. Three forms can now be described[10]: (1) the most severe, following total gastrectomy; (2) the most protracted, resulting from removal of pylorus and duodenum; and (3) a condition following removal of the distal two-thirds of the small intestine. The last variety resembles the second, but with the presence of a macrocytic hyperchromic anaemia, glossitis, and chronic diarrhoea. Clinically, indeed, the picture resembles that seen in sprue and in some cases of terminal ileitis. Experimentally it must be contrasted with the results following resection of the jejunum—namely, a mild degree of pellagra, hypochlorhydria, and, above all, a striking increase in red blood cells with a tendency to macrocytosis.[11] It is obvious that we are gradually accumulating facts as to the varied functions of the different regions of the alimentary tract, and more knowledge of its functional pathology may throw a sharp light on the pathogenesis of the anaemic states and deficiency diseases.

SUBACUTE BACTERIAL ENDOCARDITIS

A recent talk by Willius[12] is entitled "The Hapless Therapy of Subacute Bacterial Endocarditis." He points out that an occasional positive blood culture in a patient with a cardiac murmur and fever is not proof positive of subacute bacterial endocarditis. Without a doubt many instances of this type represent acute exacerbations of rheumatic endocarditis, in which from time to time streptococci in relatively small numbers are demonstrable in the blood stream. Such patients may recover without any treatment. But if the diagnosis of subacute bacterial endocarditis is confined to patients with pathognomonic signs such as embolic phenomena and splenomegaly the outlook is indeed grave, and there is little support for the new wave of optimism which is sweeping North America. Willius enumerates the systems of treatment that have had their day—immune transfusion, arsenicals, antiseptic dyes, vaccines, *x*-ray therapy over the cardiac region, artificial pyrexia, intravenous colloidal carbon, etc.—and he concludes that the present enthusiasm for chemotherapy, used alone or supported by anticoagulants or hyperthermia, should be met with scepticism. This cool outlook should be preserved in studying the recent paper by Smith, Sauls, and Stone.[13] They have summarized a number of group-studies by individuals who have treated series of cases, thus trying to avoid the fallacy of judging from isolated successes. The percentages of recoveries in these series certainly suggest a progressive improvement in results. The actual figures are as follows:

	Recovered	Died	Total
Non-specific treatment	6	628	634
Chemotherapy alone	12	186	198
Chemotherapy + heparin	5	38	43
Chemotherapy + hyperthermia ..	4	21	25
Chemotherapy + intravenous typhoid	4	17	21

Statistical analysis of these figures, which the authors unfortunately omitted to employ, shows that there is strong evidence that chemotherapy has improved the survival rate in subacute bacterial endocarditis. The data provide no evidence that heparin or hyperthermia significantly increases the survival rate above that for chemotherapy alone. There is a strong indication that intravenous typhoid vaccine does so, but one needs more cases in these last two groups. Smith and his colleagues stress the importance of early diagnosis, but we must remember Willius's hint that early diagnosis may be erroneous diagnosis. A second factor of importance is the maintenance of a high blood concentration of the drug. False hopes may be raised by the antipyretic action of sulphapyridine or by the failure of the blood cultures to show bacterial growth after the sulphonamides have been given, even though infection is still present. This error may be avoided by adding para-aminobenzoic acid to the culture medium to neutralize the bactericidal effect of the sulphonamide present in the blood when it is cultivated. Poston and Orgain[14] have found that there are very great variations in the reaction of different strains of *Str. viridans* to the sulphonamide drugs, and it is therefore desirable to test the strain with which the patient is infected against the available sulphonamides, in order to decide on the most suitable drug. There is a definite correlation between the effects *in vitro* and *in vivo*. If preliminary experiments of this kind are impossible, sulphapyridine is the drug of choice. Recovery from subacute bacterial endocarditis is in any event likely to be of limited duration and to be followed sooner or later by recurrence of infection or by cardiac failure. Using recovery in this restricted sense, chemotherapy has probably improved the chances of recovery in subacute bacterial endocarditis from about 1 in 100 to 1 in 20 or 30, and the ordinary clinician will do well to confine himself to chemotherapy with the sulphonamide drugs until there is more convincing evidence that results can be improved by the addition of anticoagulant therapy or artificial pyrexia.

INFECTIOUS MONONUCLEOSIS

In a recent monograph on the aetiology of glandular fever (or infectious mononucleosis) Wising[15] of Stockholm finds support for the assumption that a virus is the responsible agent and not *Listerella monocytogenes hominis* or a toxoplasm. Twenty-seven typical cases were studied. Cultures from blood and lymph nodes were negative. The injection of cultures of *Listerella* into rabbits and monkeys did not produce a disease picture similar to infectious mononucleosis in man. Attempts were made to transmit infectious mononucleosis in the acute phase to rabbits and monkeys; the results were negative in rabbits, but suspensions from lymph nodes produced typical mild infections in monkeys. Wising was surprisingly successful in obtaining human "volunteers" for his later experiments. (1) Four students received 20 intravenous injections of 100 million to 3,000 million *Listerella*, heated to 65° C. for two hours on two consecutive days. Their sera developed high agglutinin titres and positive flocculation reactions. The Paul-Bunnell test, which depends on the presence of sheep-erythrocyte agglutinins in amounts well above the normal, was negative. (2) Eight recently afebrile convalescents from mononucleosis and four healthy controls received intravenously 5,000 to 10,000 million heat-killed *Listerella* organisms in a single injection. Several persons developed malaise and chills, but the extent of the toxic response did not vary between the groups. (3) Five healthy medical students were transfused with heparinized blood or plasma from acute cases of infectious mononucleosis, and one developed an illness which was typical on clinical, serological, haematological, and histological grounds: the incubation period was 18 days, and symptoms decreased rapidly after the thirty-fifth day. Thus, in the experimental subject, further evidence was adduced that *Listerella monocytogenes* does not play a causal part in glandular fever. A virus may be the infecting agent, but unfortunately unfiltered and not filtered blood was used for the one successful experiment in transmission. Extirpated lymph nodes from sixteen cases were examined microscopically. No bacteria or protozoa were demonstrated, but photomicrographs revealed numerous large cells with a cytoplasm which absorbed ultraviolet light intensely. Further, the nucleoli were large and irregular and generally surrounded by irregular zones of chromatin. The author states that these changes could be explained by the presence of a virus. Nettleship[16] inoculated chorio-allantoic membranes with filtrates of the blood and nasal washings of patients and produced small white pearly growths infiltrated with mononuclear cells. Van den Berghe and Liessens[17] also used bacteria-free filtrates, and consider the agent a virus. The agent having been isolated by tissue culture of bacteria-free filtrates, the authors were with it able to reproduce disease in monkeys, which developed a typical blood picture and heterophile reaction.

The laboratory and clinical data of 20 cases of infectious mononucleosis have been reviewed by Kilham and Steigman[18] of the American Red Cross-Harvard Field Hospital Unit. Four had clinical and three subclinical icterus; liver biopsy showed parenchymatous changes in one case. The Barrett[19] modification of the Paul-Bunnell test for the heterophile antibodies which agglutinate sheep erythrocytes was positive in all cases. (This modification differentiates the antibodies found in infectious mononucleosis from the types found in "normal" human serum and in human serum following horse-serum injection.) A high lymphocytosis was observed in all cases and an absolute or relative decrease in polymorphonuclear cells in many. No treatment proved effective. The agglutination of sheep erythrocytes in this disease is strongly reminiscent of the Hirst[20] test in influenza, in which the agglutination of chicken erythrocytes provides an easy and useful method of titrating influenza virus. The fact that exacerbations in the disease are usually unassociated with increase in the agglutination titre in the Paul-Bunnell test hardly supports the view that it has any immunological basis; may not the agglutination be due to persistent circulating virus? One is tempted to speculate whether the Paul-Bunnell test with sheep erythrocytes supports by analogy the view that infectious mononucleosis is of virus origin, and whether in other virus diseases the serum of the patient will be found to agglutinate the red cells of certain animal species.

FOOD PROBLEMS IN THE U.S.S.R.

A recent review of Soviet food problems[21] shows how the U.S.S.R. in some measure was able to prepare for the loss of much fruitful territory by shifting the basis of market grain from the Ukraine to the north and east. The Russians now rely on regions in Siberia in which preparations for rapid expansion had been well advanced in 1941. By September of that year the Altai area had three times its 1940 acreage under winter crops, and there was a similar increase in other districts. By means of irrigation schemes such an area as Uzbekistan has been able to turn over 1½ million acres into grain-producing land. The Altai area is growing mainly beet, the area given to this crop having increased from 60,000 to 100,000 acres between 1941 and 1942. Two refineries deal with 250,000 tons of beet a year. This immense development has been made possible by the use of some 150,000 motor tractors and 53,000 harvester combines, involving the training of many thousands of drivers and operatives. When, after the German retreat, territory in Western Russia was reoccupied, an intensive effort was made to get the land under cultivation; and, though the setback must have been great, prompt action and strict management in future will do much to minimize losses. About 500 tractors which had been buried by the farmers were recovered; collections of seed were instituted and credits granted for the purpose of buying seed and stock. By the end of March, 1942, collective farmers west of Moscow had stored 78.5% of the season's seed, and a number of fresh cattle ranches had been set up. Allotment holdings have been taken up eagerly, especially in Leningrad, where 22,000 acres round the city are under vegetables. Rationing began in July, 1941, first in Moscow and Leningrad and then in other industrial areas. The system has been one of differential rationing. For instance, the industrial worker gets 27 oz. of bread a day and the office worker 22 oz. Bread consumption as a whole remains higher than our own. Expectant and nursing mothers receive extra butter, sugar, milk, bread, and other cereals. During siege conditions in Leningrad meat, butter, and sugar became scarce luxuries, and were diverted to the armed Forces. In the interior of the country conditions approach normal, but the population behind the fighting fronts must be suffering serious privation.

SEE HOW THEY JUMP

Some readers may recall the irritation displayed by the versatile members of the "Brains Trust" on being asked how flies take off and land. The erudite zoological member of the team dismissed the question (*a*) as being unimportant, and (*b*) as being a matter of aerodynamics. The interesting *Monthly Science News*, *MSN*, issued by the British Council (3, Hanover Street, London, W.1) recently made good this deficiency on the part of the B.B.C. entertainers by recording an interesting experiment carried out some three years ago by Prof. Edgerton of Massachusetts. Prof. Edgerton put a bit of sugar on a piece of paper. To this was attached a few feet of string, which was also wrapped round the shaft of a high-speed camera. As the camera brought the film up to running speed, it wound the string attached to the paper and eventually dislodged the paper from beneath the fly which had settled on the piece of sugar. With this ingenious and simple experiment Prof. Edgerton was able to get accurate pictures of the fly taking off. This is how the fly did it. It first of all jumped backwards into the air for about an inch and at an angle of 60 degrees to the horizontal. Once it was clear of the ground its wings began to beat, and the fly came out of reverse and went forwards. The anatomy of the fly's legs makes it impossible for it to jump in any direction other than backwards. *MSN* suggests that, making use of Edgerton's observations, fly-swatters should be able to increase their score by aiming at the back area of a fly at rest.

MEDICAL ADVISORY COMMITTEE

The Minister of Health has set up a committee to advise him on the medical aspects of problems relating to the health of the people. The members of the committee are: the Presidents of the Royal College of Physicians, the Royal College of Surgeons, and the Royal College of Obstetricians and Gynaecologists; the Chairman of Council of the B.M.A.; Dr. G. C. Anderson; Dr. J. C. Arthur; Miss Alice Bloomfield, M.D.; Dr. J. A. Brown; Mr. E. Rock Carling; Dr. J. A. Charles; Prof. Henry Cohen; Dr. W. Allen Daley; Lord Dawson of Penn; Dr. E. A. Gregg; Lord Horder; Sir Wilson Jameson (vice-chairman); Dr. W. S. Macdonald; Dr. Alan Moncrieff; Prof. R. M. F. Picken; Prof. Harry Platt; Dr. A. T. Rogers; Dr. D. O. Twining; Dr. Oscar Williams; and Miss A. L. Winner, M.D.

THE PRACTICAL MANAGEMENT OF WOUND SHOCK

BY

J. McMICHAEL, M.D., F.R.C.P.Ed.

Attempts to define "shock" are baulked in various ways. Newspapers and laymen use the word to describe any state of fright, with or without collapse, associated with injury or emotion. The older textbooks of surgery regarded it [illegible] a condition of "general depression of the vital functions" following on injury. This definition was recently put more crudely by a surgical colleague as "a state in which the patient is half dead." Since the last war the condition of low blood pressure observed in injured patients has been a subject of interest, and many definitions have limited shock to "a state of circulatory collapse following injury." This was the generally accepted definition when the present war began. Experience has revealed, however, that one important result of injury hitherto unappreciated may be renal failure, and the much-discussed "crush syndrome" has taken a prominent place as a remote consequence of injury. For various reasons it thus seems that the general term "shock" can no longer be limited to the circulatory effects of injury.

As no agreement on a classical definition of shock could be reached, there has been a great deal of confusion in the use of the term. It is this very confusion which has led to much ill-advised controversy on the value or otherwise of therapeutic measures. Some medical men, for example, have laid emphasis on the value of weak tea in treatment, as against blood transfusion. It is certainly true that, if all cases admitted to hospital after a raid are regarded as "more or less shocked," warm drinks may have a large measure of success. Those who restrict the term to cases showing low blood pressure find that a high proportion of cases do need transfusion. The only way out of this impasse seems to be the cessation of use of the word "shock" as an unqualified term.

Varieties of Shock

The following terminology may be used with advantage:

Fright, or emotional "shock" due to severe emotional strain.

Neurogenic Shock.—A state of low blood pressure with slow pulse, resembling an ordinary faint. This mild variety may be named "vasovagal syndrome." The onset is often early after an injury, and it is probably to this condition that some of the older writers referred when discussing "primary" shock. A more serious form occurs after severe cerebral injury, and may be called *cerebral shock.*

Oligaemic Shock.—A condition of circulatory collapse due to a low circulating blood volume. This condition includes the majority of cases of severe shock encountered as war casualties.

Post-traumatic Hypertension.—A cardiovascular reaction to injury recently described by Grant and Reeve (*British Medical Journal,* 1941, **2,** 294) which may simulate oligaemic shock.

Crush Syndrome.—This description is applied to renal failure which follows devitalization of limb muscles by crushing injuries. It is usually, but not always, preceded by a phase of oligaemic shock.

Toxaemic Shock.—This term may be applied to the circulatory collapse due to intense bacterial toxaemia, typically seen when a serous cavity is suddenly flooded with infected material—e.g., rupture of an inflamed appendix or a lung abscess. The blood volume in such cases may be normal.

Shock due to Defined Mechanical Causes.—For example, coronary thrombosis, massive pulmonary embolism, fat embolism, etc.

Dehydration Shock.—Occurring in diarrhoea (and ? diabetic coma).

It is apparent that by the use of such qualifying terms much of the present confusion would disappear. A common understanding of the condition under discussion might result in greater clarity when dealing with methods of treatment.

Clinical Manifestations of Shock

The various types may be discussed in order of increasing severity:

1. *Fright.*—When patients are admitted to hospital they may, on examination, look rather ghastly owing to a covering of dust, and cold extremities may give an initial impression of shock. On more detailed examination it is found that the blood pressure and pulse rate are within normal limits and that the injuries are of a minor nature. Such patients are simply suffering from fright and exposure. No treatment is required other than warmth, reassurance, and hot drinks.

2. *Post-traumatic Hypertension.*—A small proportion of patients with injuries of some severity may be found to have systolic blood pressures as high as 140 to 170 mm. Hg. The subsequent course of these cases shows that the normal pressure has been about 120 mm. Hg. As Grant has emphasized, there may be a rather thready radial pulse, which creates a false impression of circulatory collapse. Sphygmomanometer readings correct this impression. Although no active treatment is indicated at the hypertensive stage, the patients must be carefully watched, as they may pass on to a more characteristic picture of oligaemic shock. Our experience of this type of reaction has been limited to two cases, and in both the blood pressure fell to a low level, necessitating transfusion, within an hour or two of the finding of hypertension. The severity of the injury is usually in itself an indication for careful observation of these patients.

3. *Neurogenic Shock.*—In this condition there is a fall of blood pressure accompanied by a slow pulse. Two groups should be recognized:

(A) *Vasovagal Syndrome.*—This condition resembles an ordinary faint in every respect. Following on emotional stress or increased susceptibility to pain, the sensitivity of the carotid sinus mechanism seems to be altered in such a way that slowing of the heart and peripheral vasodilatation occur. The patients complain of a feeling of warmth, nausea followed by faintness, and a clammy sweat, while the systolic blood pressure falls to 50–70 mm. Hg and the pulse is slowed—e.g., to 50 a minute. It is important to remember, however, that these phenomena are compatible with considerable loss of blood from haemorrhage and that this vasovagal faint is a common consequence of venesection even if this is massive (Wallace and Sharpey-Schafer, *Lancet,* 1941, **2,** 393).

(B) *Cerebral Shock associated with Brain Injury.*—In a number of cases of severe head injury blood pressure may fall, the pulse may become slow or irregular, and various other vegetative disorders may be manifested—for example, deep, stertorous, irregular, or periodic breathing. The circulatory collapse in these cases is neurogenic in that it results from disturbance of the centres of cardiovascular control in the medulla.

Treatment of Neurogenic Shock.—In the uncomplicated vasovagal attack recovery usually follows rest in the recumbent position. In those cases which are associated with haemorrhage the blood pressure may remain low for an hour or more and the condition may pass into the more serious picture of oligaemic shock. For this reason continued observation is essential. In neurogenic collapse due to cerebral injury the condition is much more serious. Transfusion and the head-down position are both contraindicated, as they add to the risk of further intracranial bleeding. The surgical care of the head injury will dominate the picture: transfusion should be employed only by agreement with the surgeon, when the risk of precipitating intracranial haemorrhage has passed.

Oligaemic Shock

In this variety a number of well-recognized features are present, the pathological basis of which may be described as follows. Owing to loss of circulating fluid the veins are poorly filled. With deficient venous return to the heart the cardiac output drops to a low level. This in turn leads to a fall in pressure in the aorta and carotid sinus. From these reflexogenic zones vasoconstriction and cardio-acceleration are initiated. The vasoconstriction takes place mainly in the skin and splanchnic areas, leading to skin and visceral pallor. Along with this there seems to occur general increased sympathetic activity with a tendency to sweat, giving the cold skin its characteristic clamminess. Up to a certain degree of blood loss the compensatory vasoconstriction may maintain blood pressure at a level which is near normal, but the pulse will be accelerated. With further blood loss compensation fails and the blood pressure drops, with further acceleration of the heart. When oligaemic shock persists over a certain time a great danger is the development of an irreversible state in which restoration of the circulating blood volume fails to produce lasting improvement. For this reason treatment should be early, adequate, and effective.

Some Quantitative Considerations.—The reduction of blood volume necessary to produce various degrees of shock has as yet been very inadequately studied. Keith, in the last war, found that the severest cases of shock had blood volumes down to 60% of normal—i.e., a fall from 5 litres to 3 litres in circulating blood volume. Observations made by the Army Transfusion Service and by workers in the British Postgraduate Medical School indicate that blood volumes may fall much lower than this. We have observed several cases with blood volumes of 1.2 to 1.5 litres and blood pressures about 50 to 60 mm. Hg; while at the other extreme a number of volunteers have given 1,200 c.cm. of blood without much decrease in blood pressure. Further quantitative studies on this important subject are required, but meantime we may work on the assumption that a reduction of blood volume by 1 litre may be well tolerated and that in the most severe cases (B.P. below 60 mm. Hg) we may perhaps be dealing with a blood loss of as much as 3 litres. The importance of such quantitative studies is that they reveal the necessity for large transfusions (over a litre) in the vast majority of cases requiring such treatment.

Pulse Rate.—Although it might be expected that the carotid sinus mechanism would dominate in the cardiovascular reaction to oligaemia, the pulse rate is often surprisingly slow. We have already mentioned the occurrence of vasovagal attacks with pulse rates below 50 after moderate haemorrhage (1 litre), and it should now be noted that pulse rates of over 120 are rare even in very severe shock. A common pulse rate with blood pressure below 80 is 100 to 110. Further, we have observed that transfusion, while increasing the blood volume and raising the blood pressure, may be accompanied by a further rise in pulse rate. This paradoxical pulse reaction emphasizes the unreliability of pulse-rate records as giving any indication of severity, progress, or results of treatment. Increasing and fundamental emphasis is therefore laid on blood-pressure records.

Causation of Oligaemia

During the last war, and in the scanty observations made by clinical workers up to the onset of the present war, there seemed to be considerable mystery about the loss of blood. It was thought that loss of blood was not accounted for by external haemorrhage, and there was much speculation about "pooling" of blood in various parts of the vascular system. We can now state that in the vast majority of cases the diminution of circulating blood volume is due to extravasation of blood either outside the body or into the injured areas. The evidence for this is as follows:

(A) A carefully taken history often reveals quite extensive bleeding from unexpected sources. For example, one patient, whose major injury appeared to be a comminuted compound fracture of both bones of the leg, volunteered the information that she bled so much from her scalp that the pillow was soaked and had to be changed in the ambulance. Careful examination both before and during the operation often reveals enormous effusions of blood among the lacerated tissues.

(B) When serum or plasma alone is used for transfusion the whole course of the condition is very similar to that of a patient who has had, for example, a large haematemesis. Immediately after any severe bleeding the haemoglobin is not much reduced, and the usual figure is 80 to 90%. It takes a few days for plasma volume to be made up and for full blood dilution to occur, and it is only after 48 hours or more that the haemoglobin figure really does give a true indication of the blood loss. In one patient who had considerable haemorrhage among the thigh muscles following a punctured wound, and who was given a serum transfusion, the haemoglobin settled down from 86 to 48% in the course of three days. There was no evidence here of any sudden reappearance of blood from a "site of pooling" as the patient recovered from his shock. It seems apparent from the final haemoglobin figure that he had lost about half his circulating blood volume by haemorrhage. This was further borne out by the fact that it took 1,800 c.cm. of serum to restore his blood pressure from 70 to 120 mm. Hg.

It seems, therefore, that haemorrhage plays a very considerable part—in our opinion the most important part—in the production of shock.

Shock due to Plasma Loss.—In our experience this is encountered only in shock due to burns and in patients who have been subjected to prolonged crushing injuries. Again the clinical manifestations are very obvious. There is extensive oedema of the injured areas, and the haemoglobin concentration rises as high as 160%. Along with this haemoconcentration the blood pressure falls, and when serum is transfused in a quantity adequate to reduce the haemoglobin to a normal level the blood pressure is once more restored.

Shock due to Blood Loss combined with Plasma Loss.—It is obvious that injuries causing blood loss may be combined with prolonged muscle-crushing, which seems to produce the factor of plasma loss as well. In one such patient who was fully studied the initial haemoglobin figure was 100%; serum transfusion reduced the haemoglobin to 72% with restoration of the blood pressure. One and a half hours later the haemoglobin rose to 90%, indicating loss of serum from the circulation, and this was accompanied by further circulatory collapse. After further transfusion, operation was undertaken on an injured limb, when a large pool of blood containing several pints was found under the deep fascia.

The observations at operation thus established haemorrhage as a factor, while the inability to retain transfused serum meant that the capillaries in some part of the body were leaking serum constituents.

Other Factors in Shock

While loss of circulating blood volume is the dominant single factor, we should not deny the possibility that other influences may render the syndrome much more complex. These should be kept in mind as follows:

(A) *The irreversible state* must first be considered. We have seen patients in whom the blood pressure has been low (below 90 mm. Hg) for a few hours, and in whom restoration of the blood volume by transfusion failed to produce anything more than a transient improvement. It may be that the prolonged tissue anoxia has led to grave changes in the central nervous system and in other organs. Whatever the explanation, this condition is responsible for many therapeutic failures, and it should be prevented by *early* restoration of the blood pressure.

(B) *Toxaemic Factors.*—In the classification outlined it was noted that severe bacterial toxaemia could in itself produce a shock-like picture. It is apparent that infection of traumatized tissues may lead to the same result.

(C) *Crush Syndrome.*—It is noteworthy that the fall in blood pressure associated with loss of half the plasma—i.e., about 1½ litres—may be much more profound than that which follows a similar blood loss. The demonstration of grave renal impairment at an early stage in such cases seems to indicate the release of toxic substances into the circulation: these may have damaging effects on organs and tissues other than the kidneys. Reduction of blood volume may possibly be poorly tolerated when haemoconcentration is present.

Treatment

Organization.—The shocked patient calls for more continued and assiduous attention than is required in any other condition. It should be realized from the outset that these injured patients are under the care of the receiving surgeon. In order to relieve pressure on the operating teams the services of physicians skilled in transfusion technique may be employed in supervising the work of resuscitation in special wards set aside for this purpose. It should be realized that adequate nursing aid should also be available; over a period of a few hours one nurse should be at hand for each patient requiring transfusion. There is usually little difficulty in achieving this through the help of volunteers from among the nursing staff. In addition to the ordinary pulse and temperature charts, blood-pressure records are very important. Students, nurses, and orderlies may be trained to record systolic pressure.

General Measures.—Patients should be undressed as quickly as possible so that a full assessment of injuries may be made. They should be put to bed in the recumbent position; if circulatory collapse is obviously severe the head-down position should be adopted while waiting to begin transfusion. Warmth is desirable, as these patients are often chilled; but overheating is to be avoided. In a striking recent paper Blalock and his colleagues showed that overheating was definitely harmful. Not only is blood deflected to the warm skin when it is badly needed elsewhere, but the metabolism of tissues in general is increased by warmth, calling for a still greater oxygen supply. Adequate cover should therefore be given to shocked patients, but there is no need to worry unduly about cool or cold extremities.

Morphine.—Morphine should be given when indicated. It has little value as a specific therapeutic measure, but if there is a complaint of pain it should not be withheld. It is usually found, however, that patients in profound oligaemic shock do not complain of pain, though restoration of the blood pressure by transfusion is accompanied by increasing restlessness and awareness of pain. Morphine is therefore likely to be required while the patients are recovering rather than during the stage of severe shock.

Fluid Administration.—Since loss of circulating fluid is a fundamental feature of oligaemic shock, fluid replacement is necessary. If the patients are thirsty they should be allowed glucose drinks, warm tea, or water as desired. Vomiting is sometimes a troublesome feature, and in such cases tap-water may be given slowly per rectum. If these methods prove unsuccessful, deep intramuscular infusions of saline may be given into the lateral aspects of the thighs, the needles being pushed right down to the bone. A large amount of fluid may be administered in this manner.

Transfusion.—Blood transfusion is the sheet-anchor of successful treatment in oligaemic shock. Other transfusion fluids may also be used, and these are discussed below. Considerable clinical judgment is necessary to decide when transfusion should be begun, and no simple rule can be enunciated. It is obvious that in patients with very low blood pressures—e.g., below 80 mm. Hg—transfusion should be started at the earliest possible moment. Where injuries are severe, and from the history and from examination there is evidence of severe blood loss, transfusion should be begun without delay, even though the blood pressure may not be below 100 mm. Hg. Experience has shown that in such cases more serious vascular collapse may develop quite rapidly. In the less severe cases of injury a period of observation is necessary. A low blood pressure, if associated with a slow pulse, is likely to recover spontaneously; in other instances the pulse may become more rapid and the patient will pass into a state of obviously severe oligaemic shock, for which transfusion is required. Generally speaking, if the blood pressure remains at or below 90 mm. Hg for more than one hour transfusion should no longer be delayed. The danger of prolonged lowering of blood pressure is the development of the irreversible state already mentioned.

The volume of blood or blood substitute to be given by transfusion is determined entirely by the response of the blood pressure. The transfusion should not be stopped until the blood pressure has returned to a normal figure, say 110 to 120 mm. Hg. In previously hypertensive subjects it will be found that the blood pressure will go on rising towards a higher figure with quite moderate transfusion volumes, and in such patients the transfusion should be continued until a pressure of 140 to 150 mm. Hg is reached. When a normal blood-pressure figure has been reached the transfusion apparatus should not be at once disconnected but the infusion should be allowed to continue slowly as a drip: the slow drip is a precaution against a further fall in blood pressure which may result from loss of the saline part of the transfusion fluid or which may develop at subsequent operation. Arrangements should be made for the continuation of transfusion while any operative procedures are being undertaken.

Transfusion Fluids.—Blood is the fluid of choice, but there are considerable advantages in the use of serum or plasma. The latter fluids can be used without cross-grouping, and we have seen no untoward results from the administration of quantities as great as 2 litres. During the administration of serum the recipient's haemoglobin is diluted and he is rendered moderately anaemic. It is desirable, therefore, that some limit should be set to the degree of blood dilution produced by such methods of transfusion, and we regard it as unwise to reduce the haemoglobin below 60%. It is safe to give serum or plasma in quantities up to 1 litre, but if further transfusion is necessary blood should be used where possible.

Other blood substitutes include Bayliss's gum-saline, introduced in the last war. Casualties have not yet occurred on such a scale as to exhaust our stocks of blood and serum, but in such an event gum-saline would undoubtedly be used. More recent blood substitutes devised in America include solutions of pectin and isinglass. We understand that these are rather disappointing.

Reports of Societies

BACILLARY DYSENTERY IN THE MIDDLE EAST

MODERN CHEMOTHERAPEUTIC TREATMENT

At a meeting of the Royal Society of Tropical Medicine and Hygiene on Nov. 4, with Sir Rickard Christophers, F.R.S., presiding, Col. N. Hamilton Fairley, F.R.S., presented on behalf of himself and Col. J. S. K. Boyd the results of certain work carried out in the Middle East on the diagnosis and treatment of bacillary dysentery, with special reference to sulphaguanidine. Col. Fairley said that the joint investigation of Col. Boyd and himself ended in January, 1942. The analysis of data was at that time incomplete, and further data might be incorporated before the paper was published.

The outstanding feature of bacillary dysentery in the Middle East, said Col. Fairley, had been its mildness. Even with Shiga dysentery the mortality had not been as high as expected. But although the general mortality rate had been exceedingly low and the incidence much less than in the last war, bacillary dysentery continued to cause great wastage of man-power, especially as duration in hospital averaged three to four weeks.

Army Prophylaxis

At Headquarters, Middle East, the aspects on which the work had been concentrated were Army sanitation, fly control, the dysentery carrier, bacteriological types of organisms present, and specific treatment. In the Middle East fly transmission was the rule, and faecal-feeding flies abounded. In the forward areas it was the duty of the sanitary personnel to burn or treat promptly with insecticide all exposed excreta and animal carcases. Where possible in these forward areas trench latrines were immediately dug and provided with well-fitting fly-proof covers if available. Failing this, earth was immediately used to cover the stools in trench latrines, which were sprinkled once daily with powdered borax or some insecticide. It had been found that desert flies did not like entering roofed structures where it was darker inside than out. In camps curtains of fishing-net hung outside of doors and windows afforded protection even although flies could get through the meshes. Cooks and all people handling food were instructed to wash their hands regularly. Native labour presented a problem, but when latrines of the Moslem type were constructed, fly-proofed, and conveniently placed this problem became manageable.

Shiga dysentery on the average accounted for about 10% of all cases seen in the Middle East. The most common organism was Flexner II, and the next most common was Flexner VI. the old Newcastle–Manchester group. About 10% of all dysentery was amoebic (with which the present study was not concerned); no bilharzia dysentery had been seen by Col. Fairley. After dealing with the different types of exudate and the relation between these and the percentage of isolations, he passed on to the carrier problem. In chronic cases, and also in acute cases which failed to clear up in the ordinary way, sigmoidoscopic examinations were always made, and he described the appearances and varieties of ulceration seen in such examinations and discussed their significance. In certain cases of chronic Shiga dysentery ulcers surrounded by normal-looking mucous membrane were found to contain Shiga bacilli six months after the original attack.

Clinical Aspects

Most epidemic diarrhoea was dysentery. From a military point of view any person who had collicky pain followed by febrile diarrhoea with fluid stools containing flakes of mucus or mucus and blood should be regarded at once as a case of dysentery and sent away without delay. He had stressed the mild nature of most of the dysentery encountered, but with Shiga dysentery there were many exceptions. Fulminating cases were rare. He recalled one case, however, in which death occurred within 32 hours of onset. In the ordinary severe Shiga infections onset might be sudden or insidious. The former began with a rigor associated with fever, nausea, and vomiting; in the latter, severe intestinal symptoms might not develop for several days. One unfortunate feature about bacillary dysentery was that neither the mode of onset nor the febrile course necessarily afforded a reliable index to prognosis.

Complications were rare, but some were met with which had not previously been described. Local complications included perforation, intestinal haemorrhage, chronic peritonitis with effusion and pneumoperitoneum (one case); among the systemic complications were peripheral circulatory failure, renal failure, and arthritis.

The majority of cases of non-Shiga dysentery ultimately got well, in Col. Fairley's experience, with rest, copious fluids, appropriate dietary, and magnesium sulphate, but magnesium sulphate treatment should not be continued over too long a period, as it sometimes tended to keep up the diarrhoea. With regard to dietary it had been found that with milder infections milk drinks could be allowed at a relatively early stage without disadvantage.

The conclusion reached with regard to serum treatment was disappointing. He took out with him to the Middle East a specially prepared experimental batch of high-titre anti-dysenteric Shiga serum (1 c.cm. = 20,000 I.U.), and had a fair opportunity of testing its value. It certainly relieved toxic features—presumably by neutralizing circulating Shiga toxin—but its benefit was rarely more than temporary.

Experience with Sulphaguanidine

He well remembered three of the first cases treated. Two of them had been under observation for three months and no treatment had made any real difference to the ulcers. Within 14 days of beginning sulphaguanidine treatment the ulcers completely healed, and the symptoms, which at this stage were mild, entirely disappeared. In the third case, which had lasted for about six months, there was again complete healing of the ulcers within a fortnight. A much wider investigation with the drug was then undertaken, and it was applied in a series of over 500 cases. Care was taken to combat dehydration where present.

The administration of sulphaguanidine was followed in some cases by headache or nausea, and in a few instances toxic rashes and fever developed. There was not a single case of haematuria, agranulocytosis, haemolytic anaemia, or jaundice, nor did sulphaguanidine bring about obstructive effects in the kidney. In 135 proved Shiga cases which recovered under sulphaguanidine therapy there was as a rule quite early an astonishing improvement, manifested by an increased feeling of well-being, rapid relief of abdominal pain and tenesmus, and a decrease in abdominal symptoms. An early reduction of temperature and pulse rate took place in uncomplicated cases, which reached normal in one to three days. There was also a remarkable reduction in the daily number of stools, and a rapid disappearance of blood and subsequently of mucus from the faeces.

In a total of 84 cases in which Shiga bacilli were isolated Col. Fairley was able to show the results in the following tabular form:

Interval of Days between Onset and Beginning of Treatment	No. of Cases	Average Number of Stools in 24 Hours preceding Treatment	Average Time in Days after Treatment started before Stools per Day were—		
			3–5	2 or less	Formed
1–5	39	27·8	4·0	5·3	7·7
6–10	32	21·7	4·0	5·4	7·15
11–20	13	14·1	3·0	5·0	8·3

That result could be interpreted only by assuming that there was an active bacteriostatic action on the dysentery organisms in the bowel wall. Out of 12 more chronic cases, 9 were completely cured as shown by the sigmoidoscope; in 2 others a certain amount of diarrhoea persisted, and there was evidence of sluggish healing, although there were no ulcers; in the twelfth case the symptoms persisted, but there was no real opportunity of following up this case, which must be put down as a failure. In the entire series of over 500 cases there were 5 deaths; in two of these the patients were really moribund before sulphaguanidine was given and died within 24 hours. The third case received a full course of treatment, but the patient died of cerebral thrombosis during convalescence, and at necropsy the colon was found to be completely healed. The fourth patient had an advanced chronic bilateral hydronephrosis, while the fifth died of lobar pneumonia, which was either present at the time or developed shortly after treatment.

If supplies were sufficient, the therapeutic ideal from the Army point of view (Col. Fairley concluded) was that every dysentery patient should have sulphaguanidine at the earliest possible moment. The case should be diagnosed on clinical grounds, and, although specimens should be sent to the laboratory for culture and microscopical reports, the clinician should not await the return before beginning treatment. Such treatment would be a means of saving life in a number of Shiga cases; it would shorten the stay in hospital of the average dysentery case; and would largely eliminate carriers. Sulphaguanidine, good as it was, might not be the ideal drug for dysentery; it was expensive and had to be given in large dosage. Two other drugs were now under trial—sulphasuxidine and sulphamethazine—and it was possible that these or analogous compounds in the future might be even more useful. Both Col. Boyd and he felt convinced that in drugs of this type there was available for the first time a specific agent for the cure of bacillary dysentery; since dehydration occurred in this disease it was essential that such drugs should not produce renal blockage.

Discussion

Dr. R. CRUICKSHANK said that for the laboratory diagnosis of bacillary dysentery a medium had now been found which was a great advance on McConkey's. This was desoxycholate acetate, and with this it had been found, as Col. Fairley's work had shown, that the convalescent carrier was much more common than had been originally supposed. As for the new drugs in treatment, sulphaguanidine was less effective with the Sonne infection than with Shiga. He had had an opportunity of trying sulphasuxidine and had found it more effective than sulphaguanidine in dysentery of the Sonne type.

Dr. H. J. SMYLY, who had lately returned from Occupied China, said that in December, 1941, he received out there 5,000 half-gramme tablets of sulphaguanidine for clinical trial, and when summer dysentery set in he arranged to carry out a systematic investigation with the drug. The average mild cases which came in on the third or fourth day and cleared up after a few days with rest and simple treatment were excluded. The cases selected were those of young children under 10, cases of less than 24 hours' illness, severe cases with more than 20 stools a day, and chronic cases of over one month's duration. The doses given were initially one-tenth gramme per kilo body weight, and then half of this every four hours day and night until the stools were fewer than five a day. All the acute cases improved rapidly, the early cases usually within the first few hours, and these were apparently well within three or four days But one chronic case—a man aged 30 who had had dysentery for two years—showed no improvement whatever, although he had had sulphaguanidine for the exceptionally long period of 16 days.

Sir Philip Manson-Bahr said that he had used sulphaguanidine for over two years in a good many cases of chronic bacillary dysentery and also of colitis. He was a bold man who would say that he had a cure for ulcerative colitis, which of all cryptic diseases was most cryptic, but he conceived the idea of injecting sulphaguanidine per rectum—it was very well retained—and, watching the cases by means of the sigmoidoscope, he had become rather confident about some of the results. In some cases of chronic bacillary dysentery the results were dramatic.

In the course of the further discussion Lieut.-Col. Boland, R.A.M.C., recently returned from the Middle East, expressed a more cautious view. His experience of one year out there without sulphaguanidine and one and a half years with it had left him with an open mind. He still thought there had not been a sufficient number of controlled cases to permit an estimate of the exact effect. Supplies of the drug also had been rather limited. Cases of dysentery in the Middle East were comparatively mild, and the mortality was low. There should be a large-scale experiment in which considerable numbers of cases were treated with the drug while others served as controls.

Correspondence

Physical Treatment of Acute War Neurosis

Sir,—Dr. Sargant's (*Journal*, Nov. 14, p. 574) emphasis on the practical value of physical as against psychotherapeutic measures and environmental readjustments, in relation to their greater facility of use and rapidity of action, is especially applicable to an army in the field or under conditions prevailing in an expeditionary force.

Practical experience of the psychiatric casualties occurring in the M.E.F. during the last two years has borne out very strikingly the great importance of early and adequate physical treatment in the acute war neurosis. In the great majority of cases of acute war neurosis rapid decisions have to be reached upon three questions—whether the case requires evacuation from a forward area; whether treatment is likely to prove beneficial in a reasonable time at an ordinary base hospital; or whether, in view of the exigencies of the situation and the pressure on accommodation, a more complete evacuation is necessary. The necessity for reaching a final decision on these points makes physical measures of treatment a matter not so much of choice as of necessity.

The comparison between the "acute abdomen" and the "acute neurosis" in its relation to the urgency of treatment necessary, and in the effects of delay in instituting such treatment upon the ultimate prognosis, was shown sufficiently strikingly throughout the whole period under review. The patient who was treated within a few hours generally showed a correspondingly good prognosis, whilst the longer the delay in commencing treatment the more unfavourable the prognosis became from the point of view of return to full duties, especially in a forward area. Unfortunately, although the importance and significance of these factors were well recognized in theory, the problem of carrying them into practice under the conditions of warfare actually prevailing presented great and, at times, apparently insurmountable difficulties.

The most striking features of desert warfare in relation to psychiatric casualties were: (1) the extreme fluidity and mobility of such warfare, at least during the actual campaign; (2) the long and arduous lines of evacuation; (3) the extreme physical strain and mental stress involved during this evacuation.

The responsibility of providing the immediate treatment for the battle neurotic lay, and lies, with the regimental medical officer in a forward area; and, as a corollary, the necessity for ensuring that such medical officers have an adequate knowledge of the principles of early treatment and, equally important, an adequate supply of drugs to carry such principles into effect, becomes a matter of very great importance. The ideal choice of drugs for the medical officer in a forward area is, of course, debatable, and cannot be discussed here. In any choice of drug the essential features would appear to be standardization, low toxicity, small bulk, and simplicity of administration.

In practice, two main groups of cases were met with in a base psychiatric centre: (1) The more usual group, in which the neurosis had been developing during a lengthy evacuation lasting several days, and in which treatment had either been intermittent or, as in some cases, not given at all. (2) The group where the acute neurotic was admitted within a few hours—following, for example, severe air raids, or with naval cases. In the latter cases treatment was carried out on the general lines described by Dr. Sargant—usually by a combination of luminal and paraldehyde. In the former the methods of prolonged narcosis were more frequently employed. In both groups the necessity for distinguishing between the true battle neurotic as such and the "exhaustion state" was important, the latter responding rapidly to simple sedation and the more routine measures of physical treatment—a warm bath, a hot drink, a comfortable bed, and general care and attention.

Several practical difficulties occurred in the actual administration of physical measures of treatment; for example, in prolonged narcosis several cases of collapse and hyperpyrexia of an alarming type occurred, even with relatively small dosages and with skilled nursing care and attention. The danger of prolonged narcosis—sufficiently real, as Dr. Sargant points out, in the ordinary course of events—becomes considerably intensified under tropical or subtropical conditions. On several occasions fairly intense aerial bombardment occurred in close vicinity to psychiatric centres; the value of physical as against purely psychotherapeutic measures became especially apparent at such times.

The importance of the patient's original personality and constitution is, as Dr. Sargant states, of very great significance, and was very strikingly emphasized in a series of 350 cases of acute war neurosis analysed at the psychiatric centre which I commanded. The effect of an unfavourable constitution under varying degrees of battle stress was brought out statistically in quite a dramatic manner. The use of intravenous barbiturates in the removal of the conversion symptoms of the hysterical reaction was found of very great value, and here, also, it was found the earlier the treatment was carried out the more satisfactory the prognosis became.

Convulsive therapy was used to an increasing extent, both in the depressive states described by Dr. Sargant and in certain hysterical cases; the results were most encouraging, and the risks of fracture regarded as negligible—no complications arose in any case in our series.

In conclusion, I could summarize our experience in the M.E.F. as follows: (1) It has emphasized the vital importance of physical measures of treatment. (2) The physical measures of treatment advocated in Dr. Sargant's paper have proved of the greatest value in the treatment of battle neurotics. (3) Early and adequate treatment is of paramount importance. (4) Certain practical difficulties exist in the administration of physical methods of treatment in a theatre of war.—I am, etc.,

H. B. Craigie.
London, S.W.7 Major, R.A.M.C.

Haemolysis in Causation of Erythroblastosis Foetalis

Sir,—I have read with great interest the paper by Messrs. K. E. Boorman and B. E. Dodd and Dr. P. L. Mollison on the clinical significance of the Rh factor (Nov. 7 and 14, pp. 535, 569), particularly that part which deals with erythroblastosis foetalis. The Boston school (Blackfan and his colleagues) has maintained that erythroblastosis foetalis is a primary condition and the cause of icterus gravis, hydrops foetalis, and congenital haemolytic anaemia, whereas my colleagues and I have held the view that it is the result of haemolysis, and therefore a symptom and not the cause of these syndromes. When I last saw the late Dr. Blackfan in 1937 I discovered that our arguments had somewhat shaken his views; since that time, chiefly as the result of the work of my colleague, Dr. H. S. Baar, on the metabolism of haemoglobin (shortly to be published in the *Archives of Disease in Childhood*), we have obtained other data which support the theory that haemolysis is the underlying factor in the disease.

When I realized that Levine and his colleagues had produced evidence that iso-immunization was the cause of erythroblastosis foetalis, I endeavoured to obtain some anti-Rh sera to test their conclusion. I was unsuccessful in my attempts, but I am glad that the writers of the paper were more fortunate. Paediatricians in general and my co-workers in particular are greatly indebted to them for their work on this subject. They have produced evidence which strikingly supports our thesis, but, even more important, have devised a method for determining whether subsequent children are likely to be affected by erythroblastosis foetalis or not, and made a real contribution to the treatment of the disease. There still, however, remains unsolved the greatest problem in treatment —namely, the prevention of those ghastly sequelae, spastic diplegia, cirrhosis of the liver, and bone changes, which so frequently occur in this disease, and which often make the paediatrician regret that he has saved the child's life.

Since the thesis that erythroblastosis foetalis is the result and not the cause of this disease may now be accepted, would it not be better and more accurate to adopt the terminology suggested by Hawksley, Gittins, and myself (*Arch. Dis. Childh.*, 1933, **8**, 159) and speak of the condition as haemolytic anaemia of the newborn and subdivide it into three clinical forms: (*a*) with hydrops foetalis, (*b*) with icterus gravis, (*c*) without oedema or icterus?—I am, etc.,

Birmingham. LEONARD G. PARSONS.

Bacteriophage Treatment of Bacillary Dysentery

SIR,—Surg. Cmdr. D. C. Wilson (July 18, p. 81) makes certain remarks on my article (June 13, p. 719) which I trust I may be allowed to reply to.

He makes the point that my figures deal only with death rates (which, of course, was all I set out to deal with) and not with duration of illness; and on the strength of this he states that the aim of all three Services is "to return a fit patient to duty at the earliest possible moment." Many Alexandrian onlookers, who sometimes see more of the game than the players, will be astonished at this gratuitous statement. Actually my theme has always been that there is no need for other than a minimum of Service dysenteries ever reaching hospital. This latter occurs usually when they have passed to the stage named by me "neglected dysentery" (*B.M.J.*, 1941, **2**, 280), with resulting greater incapacity and need for longer sick and convalescent leave than if their dysenteries had never been allowed to develop into full-blown attacks. *Preventive development* of dysentery from pre-dysentery phases, like "Gyppy tummy," could—I feel every confidence in asserting from civil experience—be easily achieved by making available adequate supplies of good phage preparations at all advanced Navy, Army, and Air Force units, for administration on the first appearance of intestinal upsets of a pre-dysentery character. Has Cmdr. Wilson not, in his own words, confirmed that "civilians in Alexandria are so 'phage-minded' that to my knowledge they treat themselves with bacteriophage on the slightest suspicion of 'Gyppy tummy'"? Therefore, I think I am in a position to set his mind at ease regarding duration of illness, feeling sure that the adoption of a sound phage policy, such as outlined, could effect more in the way of improving this aspect of the situation than whatever measures may hitherto have been at work.

Cmdr. Wilson refers to a trial, in which he took part, of phage therapy in a small number of dysentery cases in an Alexandria Service hospital, from which he concludes that there was not enough "variation in hospital time" between the phage-treated and the control groups "to justify the continuation of the bacteriophage treatment." The inference here is, of course, that phage did not live up to what was expected of it, and proved no better than "the then standard treatment of sodium sulphate and fluids." The inference is misleading in that the experiment, in my estimation, was doomed to failure from the start; and the description given of it deals with no more than the opening act—"curtain raiser" might be a juster term—since, Cmdr. Wilson will recall, the performance was stopped by superior military orders before it had got properly under way. This helps to explain the challenge of my *B.M.J.* letter (1941, loc. cit.), which challenge still remains open.

Finally, Cmdr. Wilson reports that by the introduction of sulphaguanidine in the spring of 1941 a reduction in the duration of illness to 11 days from the onset was achieved, which result "appeared to make the further trial of bacteriophage superfluous." I hope Cmdr. Wilson will forgive my disillusioning him, but the facts are that statistical analysis of the recent authoritative Army figures of Cols. N. Hamilton Fairley and J. S. K. Boyd (*Lancet*, 1942, **1**, 20) and of my own figures of 13 years ago (*Lancet*, 1929, **2**, 273) reveals that sulphaguanidine presents no advantage whatsoever over phage in its rate of cure of the acute disease. Moreover, can the sulphonamides be administered with impunity to provide "preventive development" of full-blown dysentery in the same way that phage can? If so, why then, as to-day's "favourite," are they not made available at once and used (which in vain I have advocated should be done with phage) where they are most needed—the front line of all three fighting Services?—I am, etc.,

ARTHUR COMPTON,
Director of Laboratory Service, Alexandria Municipality.

First-aid for Fractured Spine

SIR,—It is with deep regret that I read of the tendency to instruct first-aiders to carry cases of fractured spine in the supine position. There is, of course, no doubt that, if carefully handled, a fractured spine can be transported safely in this position, but it entails expert handling on every occasion by skilled first-aiders. The question arises, Is this expert attention always present, and, if so, are there always the time and the facilities (e.g., during air raids) to ensure that the natural contour of the spine is rigidly maintained and that no flexion movements of any kind take place? My own experience tells me that often there is no time for attention to small details of this sort and that consequently irreparable damage may be done by injudicious handling. Should not, therefore, the first-aider be instructed to carry the patient in that position where harm is less likely to result—namely, the prone position? The whole value of this method lies in the fact that the dangerous movement of flexion is guarded against during transport. This danger is always present, and its liability to occur can well be appreciated when one considers all the movements often necessary to remove a patient from a demolished or partly demolished building on to the stretcher outside. It is these manipulations that may have such serious consequences should transport be carried out in any position other than the prone.

As regards the difficulty in diagnosis, the main duty of the first-aider is to treat the most important condition arising out of the accident. He is not concerned with accurate diagnosis. In the case in question, the patient will readily inform the first-aider as to the site of his pain, and should this be anywhere along the vertebral column no further investigation should be necessary; the patient should immediately be turned into the prone position. Quite apart from the advantages detailed above, considerable relief from pain and much comfort are attained by this change of posture.

To all rules there are, of course, exceptions, and in this case one might argue that patients with fracture of the cervical spine are better carried on their backs. This is quite true, but there is still little difficulty for the first-aider as regards diagnosis because these cases fall into two simple groups: first the fracture-dislocation, where the patient is usually unconscious and beyond treatment; and, secondly, the subluxation, where the main complaint is pain in the neck and limitation of movement. In the latter case the first-aider should have no difficulty in instructing the patient to lie flat on his back with a small pillow in the nape of his neck.—I am, etc.,

DESMOND K. MULVANY,
Hospital of St. John and St. Elizabeth Surgeon, E.M.S

SIR,—The prone position in the emergency treatment of fractured spine has always given me the impression of being of more theoretical than practical value, and I was interested to read about Lieut.-Col. J. L. Moir's method of transport in the supine posture (Oct. 31, p. 529), which appears to be of definite advantage to the first-aid worker.

The supine position is, I think, the method of choice not only because it is simpler from the first-aider's point of view but it is much safer and more comfortable for the patient. The diagnosis at the time of injury or in the casualty department of a hospital is often difficult and therefore often incorrect. Fractured pelvis, with or without abdominal complications, and fractured ribs are frequently the cause of error, and in such cases the prone position can only be harmful. Fractures of the spine may be complicated by head injuries, fractured limbs, and visceral injuries; transport of these patients in the prone position is contraindicated. At a recent large-scale Home Guard exercise I attended, many "fractures of the spine" were admitted in the prone position, which was difficult to maintain even in these uninjured "patients." Others treated in the supine posture were much more comfortable.

I consider it to be an advantage if the patient on arrival in hospital is fixed on a special frame such as the one I described (*Journal*, March 4, 1939, p. 444), which holds the spine in a moderate degree of extension and yet allows nursing and transport without disturbing the fracture. The principle is similar to that of the Thomas splint in the first-aid treatment of fractures of the femur. Unless some form of splintage is adopted the patient is moved bodily on several occasions from one site to another without adequate fixation of the spine; four transferences are needed for *x*-ray purposes alone.

Watson-Jones first advocated the prone position in the emergency treatment of fractured spine in 1931, and it has been widely adopted since. I feel that after this extended trial the time has come to assess its practical significance in first-aid work.—I am, etc.,

Pinderfields Emergency Hospital. GEOFFREY HYMAN.

SIR,—As a "mere" physician whose waning energies wartime conditions have directed to the task of teaching first aid to Home Guard and A.R.P. personnel, I was interested to read the letter of Mr. Thomas Stowell on first aid for fractured spine in the *Journal* of Nov. 21. I think many will regret that he did not ask for space for details of his methods. I hope he will also give us the benefit of his experience in teaching first-aiders how to diagnose the presence of fracture. It is very difficult to teach diagnosis of any injury; that of spinal injury is the most difficult of all. I am sure that Mr. Stowell does not intend to imply that first-aiders ought to diagnose fractures which "in the absence of repeated *x*-ray examinations are overlooked until later disabilities arise."—I am, etc.,

Downton, Wilts. J. C. MATTHEWS, M.D., F.R.C.P.

Sulphonamides for Gonorrhoea

SIR,—Dr. M. R. Soni (Nov. 21, p. 617) says that a few years ago I "stated that it is better to wait until the attack [of gonorrhoea] has lasted three weeks before starting treatment with any of the remedies [i.e., sulphonamides]." It is not strictly correct to say that I "stated, etc." In my letter to which Dr. Soni refers (*Journal*, 1938, 2, 91), I said, "On the strength of this evidence, I suggest that, etc.," and the conclusion of the same paragraph indicated, I hoped, that the recommendation was rather tentative and put forward as a basis for discussion. I still believe that the suggestion was sound as *applied to any sulphonamide remedy which had been tested at all extensively then*, but very soon afterwards it became clear that sulphapyridine was so far superior to sulphanilamide and uleron that no wait was necessary. As I had felt that the suggestion or recommendation was tentative, no public recantation seemed necessary. I hope to profit by this error of omission in future.

Dr. Soni challenges my statement that there is good evidence that administration of 5 g. sulphathiazole on two successive days eradicates gonorrhoea, in males at least, in over 90% of cases, and to prevent any misunderstanding I should like here to cite briefly the evidence which I had in mind: I had already circularized it to directors of V.D. clinics in England.

Prof. G. Miescher, Zurich (1940), as a result of a systematic trial of nine schemes of dosage, arrived first at a one-dose cure and later (1941), in collaboration with Schnetz in a paper which disclosed very careful study of the cases, recommended 5 doses of 1 g. each at intervals of two hours on each of two successive days. With this scheme they claimed 55 cures in 56 cases. Miescher's work was evidently taken seriously by some German Army medical officers. B. Mörschhäuser (1942) reported that with 10 tablets on each of two successive days the relapse-rate in 731 cases had been 5.4%. W. Heyn (1942), in 250 cases treated with 10 tablets the first day and 8 the next, had 10% of relapses. Taggeselle (1942) reported 12% relapses in 110 cases treated with 9 tablets a day for 2 days.

Since dispatch of the letter criticized by Dr. Soni I have found three other references which testify to the powerful effect of sulphathiazole in sufficient dosage. H. Haxthausen, Denmark (1941), reporting on 310 cases of complicated and uncomplicated gonorrhoea, said that in the uncomplicated ones 6 g. daily for two days had yielded 87% of cures in males and 93% in females. J. P. Pappas, U.S.A. (1942), claimed cures in 23 of 28 cases of previously untreated acute gonorrhoea in soldiers treated each with a single dose ranging from 5 to 7 g. H. Pfisterer (1941) reported 95 cures in 100 cases treated by Miescher's two-day method.

The cases in the reports quoted above appear to have been under close control, and this probably eliminated one source of error in many civilian observations—the patients' failure to take the prescribed doses.—I am, etc.,

London, S.W.1. L. W. HARRISON.

Reporting of Deaths to Coroner

SIR,—In the *Supplement* of Sept. 12 (p. 25) there appeared a most interesting opinion as to the reporting of deaths to the coroner. I am not concerned with the circumstances that led to that opinion being sought or given, but I venture to submit that, without careful appreciation of the words used, the opinion may be misunderstood.

The preamble that leads to the opinion states that the coroner *asked* for certain cases to be reported to him; the opinion deals with the matter in terms of the coroner having or not having a lawful right to require the information. The answer given does not exactly correspond with the question that appears to have been asked, and it is in that aspect of the matter that confusion of thought may arise.

It is fundamental to a coroner's jurisdiction that he be informed of a death: before being informed he has no powers. As the opinion points out, apart from a few statutory examples (deaths in mental institutions, foster children, etc.), there is no statutory duty imposed on any person to report deaths to the coroner. By common law, however, there is a duty on any person who knows that a death should be investigated by the coroner to report the fact of that death to the coroner or to the police. And in this connexion it should be remembered that a medical man, with his scientific knowledge and his keener appreciation of the facts, is in a better position to exercise this common-law duty than the average layman.

Under the law relating to the registration of deaths a doctor is required to give a medical certificate as to the cause of death to the best of his knowledge and belief; it is said that he should give a certificate even though the death be violent, since there is no legal sanction that makes any provision absolving him from the duty that statute law has cast upon him. Strict adherence to legal procedure, then, would require that the practitioner on the death of a patient whom he has attended during his last illness should issue a certificate of the cause of death (if he knows it) and at the same time report the case to the coroner if it is one which should be reported. If he does not know the cause of death he cannot issue a certificate, for the wording of Section 3 of the Coroners Act of 1887 casts upon the coroner the duty to inquire into all deaths the cause of which is unknown. If the doctor gives a certificate in a case that should be, but has not been, reported to the coroner, the registrar of deaths, when he receives the certificate from the relatives, is unable to register the death, but has a duty to report it to the coroner. In such a case he cannot register the death until he obtains from the coroner the latter's decision and conclusion. Failure on the part of the medical man to report direct to the coroner will, therefore, involve a delay which may aggravate and distress the relatives of the deceased.

Recognition of this avoidable cause of delay led to the initiation some 12 years ago in my district in London of a system whereby hospitals (a few at first) were asked if they would report to me certain classes of cases direct, instead of sending the relatives with an indifferent certificate to the registrar, who might feel unable to accept it. This system has worked well and has gradually been extended, but it is essentially voluntary and it has never been suggested that there is any legal compulsion behind it.

The effect of reporting to the coroner deaths occurring within 24 hours of the administration of an anaesthetic places upon his (the coroner's) shoulders the responsibility of decision. In the opinion of the learned counsel, the coroner rightly "requires" the information. This is higher than I assessed it and I am grateful to find that I am so well supported and, indeed, carried forward. The reporting of deaths which occur within 24 hours of admission to hospital is a valuable safeguard against unexpected elements and contingencies. It need hardly be pointed out that it is in no sense a reflection upon a hospital that a patient should die soon after admission, but it may well be that a patient should have been sent in much earlier, or that prior treatment has been inadequate, or that there may have been neglect of the patient by himself or others before his admission to hospital. From the coroner's point of view all these are matters of much importance. Incidentally, I have known many cases of criminal abortion, suicide, etc., which have unexpectedly been brought to light in this way.

While, therefore, I think we must all be grateful for the publication of counsel's opinion, it would be wrong to encourage any thought that it indicates a serious divergence of outlook between the coroner and the medical profession. Both of them have their parts to play in a public service that has a great public value, and voluntary co-operation within the legal framework between doctor and coroner is as much to be welcomed in this as in any other sphere of public activity.—I am, etc.,

W. B. Purchase,
London, N.W.1. Coroner, Northern District, County of London

Tetanus

Sir,—In his recent letter (Nov. 21, p. 619) Dr. J. H Hannan suggests that it is unnecessary to give antitoxin in tetanus because if the spasms can be controlled the body will produce its own antitoxin in due course. I should like to comment on this view, because, although it is true of some mild cases, it would be unwise to assume that it applies to more than a minority.

When a case of tetanus is first seen some toxin is acting on the nervous system (I will call this "fraction A") and there is no evidence that this can be neutralized by antitoxin, more is circulating in the blood and lymph (fraction B) and can probably be neutralized by antitoxin, and still more is being formed in the wound (fraction C), where its potential threat can be met if, when it is absorbed, there is plenty of circulating antitoxin to meet it. The danger of continued absorption from the wound is real and depends on its nature, severity, and the degree of infection. Recovery depends first on whether a lethal dose of fraction A is already acting on the nervous system before antitoxin is given. If this is so the prognosis is hopeless and death will occur whatever is done to control the spasms. Happily in a high proportion of cases this is not so, and it is probable that a large dose of antitoxin neutralizes fraction B and stops further absorption of fraction C, so preventing a lethal dose. After this, if spasms can be controlled and death by exhaustion prevented the patient should recover.

When a patient is first seen it is impossible to say how much toxin has already been absorbed and how much is still present and being formed in the wound. Some cases, of which the one quoted by Dr. Hannan is an interesting example, have only absorbed a sublethal dose, and if no more is absorbed from the wound the patients will recover by their own powers of resistance. Because it is not possible to distinguish these with certainty when they are first seen it is desirable to give a large dose of antitoxin as soon as possible to every case of tetanus. I think that to try to pick and choose those which need and do not need antitoxin will increase the mortality.—I am, etc.,

Cambridge Leslie Cole.

Prevention of Small-pox

Sir,—Dr. Arthur Howard (Nov. 14, p. 587) says: "The letter on vaccination against small-pox from Dr. Killick Millard (Oct. 31, p. 530) is typical of the prejudiced point of view of present-day anti-vaccinationists. It contains several misstatements which should be corrected." If Dr. Howard really thinks that I am an anti-vaccinationist he is certainly much mistaken. Few living men can have spent longer hours pleading with persons who were opposed to vaccination to get vaccinated—I refer of course to actual small-pox contacts—than I have done. Very many of these I have succeeded in convincing and have personally vaccinated them.

As regards my alleged misstatements, Dr. Howard specially emphasizes my contention that vaccination is a much more serious operation than immunization against diphtheria. He claims that in his experience "it causes considerably less discomfort and incapacity than the usual injections for immunization against diphtheria." I can only reply that Dr. Howard's experience is quite contrary to my own, and I have had much personal experience of both forms of inoculation. I can only imagine that his experience has been either very small or very exceptional. I think that few medical men will agree with him.

Dr. Howard concludes by urging that a campaign should be started for universal vaccination on the same lines as that now being conducted for immunization. Has it ever occurred to him that for nearly a century this country attempted to control small-pox by universal vaccination and signally failed; that India is still attempting to do so and has failed even more signally, so that small-pox in India is still a terrible scourge, causing many thousands of deaths every year; that for the past half-century we in this country have virtually abandoned the attempt to secure universal vaccination, yet small-pox has all but disappeared and has quite ceased to affect our mortality returns? Diphtheria, on the other hand, still causes thousands of deaths every year, and immunization is still on its trial. The case for universal vaccination against small-pox is, therefore, entirely different from that for mass immunization against diphtheria.—I am, etc.,

Leicester. C. Killick Millard

Riboflavin Deficiency

Sir,—I was interested to read Dr. H. Scarborough's account (Nov. 21, p. 601) of his investigations of the ocular signs in riboflavin deficiency, and his description of three cases showing the fully developed ariboflavinosis syndrome. It seems probable that cases of this deficiency are now more common than a review of the literature would indicate. May this not be due to the fact that under wartime conditions we are eating far more carbohydrates and far less proteins and fats than before, and that our vitamin intake is also reduced to a minimum? In all three cases described there appears to have been either some deficiency in absorption or a failure of storage or utilization of the vitamin, the first patient having had a gastric ulcer, the second steatorrhoea, and the third pernicious anaemia superadded.

According to Dr. V. P. Sydenstricker (*Amer. J. publ. Hlth.*, **31**, 344) when you get an excessive carbohydrate intake with a deficient absorption of vitamin or a failure of storage or utilization, the stage is set for a deficiency in one or other of the co-enzymes necessary for starch metabolism.

Apparently the ocular symptoms are among the earliest evidence of riboflavin deficiency, and the striking result of replacement therapy is well illustrated in a case which I saw recently. A married woman aged 43 consulted me in September last complaining of double ptosis, photophobia, progressive dimness of vision, and ocular fatigue; her eyes itched and felt "heavy," and she herself felt nervous and irritable and was easily tired. She had none of the classical signs (fissured lips, cheilosis, glossitis, seborrhoea, etc.) of ariboflavinosis, but had recurrent styes and "ulcers of the gums at about the period times." She had a well-marked cutaneous rosacea, and had complained of dyspepsia for some time. Nine months ago she underwent *x*-ray examination and a benign duodenal ulcer was revealed. She had been put on a diet and had very little meat but plenty of bread-and-butter, potatoes, and Benger's food. Mr. Harold Levy was consulted for her eye symptoms; he diagnosed superficial keratitis and suggested riboflavin therapy. She was given 2 mg. riboflavin orally and 1 mg. riboflavin by injection daily. The response was immediate, and after one week her ocular symptoms improved. Within a fortnight she felt perfectly well in every way and herself volunteered the statement that she had more energy and the greatest sense of well-being that she had had for months. The cutaneous rosacea was only slightly affected.—I am, etc.,

Muswell Hill, N.10. I. S. FOX.

Shock Treatment in Psychiatry

SIR,—I have read your leading article on shock treatment in psychiatry (Oct. 3, p. 397) and followed the correspondence with great interest, and fully agree with those who deplore this form of treatment as a panacea. I feel it is misleading to compare shock treatment with malarial treatment of G.P.I., for in the latter the pathology is reasonably well defined, while in the former it is still an unknown factor.

If we assume that the symptom is the "total" reaction of the individual towards the "total" environment, then an isolated form of treatment such as E.C.T. without any psychotherapeutic intervention is liable to be of only temporary value.

We have all been able to observe how in any form of shock treatment the patient becomes more accessible and able to form a transference relationship with the physician. This point is stressed by Dr. H. Pullar-Strecker (Nov. 21, p. 619) when discussing insulin treatment, and he also emphasizes the value of psychotherapeutic encouragement.

May not one of the factors in convulsive therapy be a psychological one—i.e., the patient has experienced and successfully passed through a "catastrophic experience," which may be interpreted by him as an atonement for the fantasied unforgivable sin which he has committed.—I am, etc.,

Bishop's Stortford. D. N. HARDCASTLE.

SIR,—Dr. F.-T. Thorpe says (Sept. 5, p. 281) that the "beneficial effect of shock therapy in the treatment of the emotional mental disorders is now so firmly established," etc. May I refer him to your annotation on "Brain Damage in Shock Treatment" (May 30, p. 674) and also to Dr. William Sargant's letter (*Lancet*, Sept. 5, p. 293) under the heading of "Recoverable Schizophrenia." In the New York State Hospital "a thousand schizophrenics treated with convulsive therapy did even worse than an equivalent control group left untreated, while over a thousand cases treated with insulin did three times as well." There is much more to the point. I understand from Dr. Sargant's letter that he thinks that, if it is suggested that insulin is now superseded by convulsive therapy, it would be disastrous for the patients concerned. If that is his opinion, I heartily agree with him.—I am, etc.,

Salisbury. HORACE HILL.

Convulsions under Trilene Anaesthesia

SIR,—Dr. Ysobel Garland's account of convulsions under trilene anaesthesia (Nov. 21, p. 607) resembles in some ways a recent experience of mine. The patient was a woman of 58 who had had no previous operation or illness of note. She had morphine 1/4 grain and atropine 1/100 grain an hour before operation, which was for removal of a simple cyst from the right breast. Trilene was the only anaesthetic given, and was administered by the open method on a single layer of Turkish towelling on a Schimmelbusch mask. About 2 drachms were required for induction, which took five minutes. When the patient reached stage 3, plane 1, a layer of Gamgee tissue was interposed between the mask and the face and a pharyngeal airway inserted. Ten minutes after beginning the anaesthetic, when 2½ drachms had been given and the patient was still in the same plane of anaesthesia, cyanosis suddenly developed, respiration stopped, and clonic contractions, confined to the right side of the body, started and lasted about ten seconds. The anaesthetic was stopped, the head lowered, artificial respiration started, and O_2 and CO_2 administered. Breathing was resumed in about 1½ minutes; the operation was finished in a further 20 minutes, anaesthesia being maintained with a further 1½ drachms of trilene without further untoward incident. The pulse was steady and full during the time of respiratory arrest, though somewhat rapid. The patient's temperature was normal throughout both before and after operation, and recovery and convalescence were completely uneventful. It is my impression that such incidents with trilene are due to the effect on the respiratory centre of too strong a concentration of the anaesthetic suddenly inhaled.—I am, etc.,

Nelson, Lancs T. D. CULBERT.

Tonsillectomy

SIR,—One must agree with Mr. T. B. Jobson (Oct. 31, p. 512) that the use of the guillotine requires long practice and that there are still cases which may defeat even the most expert. To reduce this number to the minimum I have found the following procedure, which I have not seen described, very useful in adults and occasionally in children.

The smallest guillotine through which the tonsil can be everted is used and placed so as to avoid both pillars. The tonsil is pushed through with thumb or forefinger and the guillotine is closed. If then a dimple appears when traction is applied one recognizes possible danger of tearing or of buttonholing to the anterior pillar. With a fairly sharp instrument one can break or cut through the strong fibrous bands. The instrument is kept close against the lateral surface of the guillotine and the bands cut through until the dimple disappears. One may then shell out the tonsil as one does in a child without danger of doing damage. A useful instrument for the purpose is a septum separator sharpened with a file. My results with this method are definitely better as regards haemorrhage, appearance, and after-pain than by dissection.

Mr. Norman Patterson's plea (Nov. 14, p. 589) for complete removal of the adenoids is a timely one. It is sometimes said that removal of tonsils and adenoids does not stop the constant succession of "colds" which many of these children suffer from. I would suggest that if a surgeon has more than 1 or 2% of children continuing with colds he should conclude that he is leaving some adenoid tissue behind. A small percentage of these cases are due to sinusitis, which, in the absence of adenoids, clears up as a rule with appropriate treatment. The important thing is to put a finger in the nasopharynx and feel that all the adenoid has been removed. If some is left it can be removed by whatever method the surgeon prefers. Very often the small soft portion at the entrance to the posterior nares can be most easily removed with the gloved finger-nail.

Whatever anaesthetic is given it should allow time for the surgeon to *see* that the tonsils are completely removed and to *feel* that the adenoids are also completely removed.—I am, etc.,

Manchester. E. S. BURT HAMILTON.

Sedimentation Rate

SIR,—During the last twelve months, while I was masquerading as a rural practitioner in Norfolk, I took the opportunity of exploring the usefulness of the sedimentin index in general practice. I found, *inter alia*, that although theoretically the joggling of a car travelling along country lanes is not ideal for the peaceful process of sedimentation, in practice it was amazing how little it affected the maximum velocities. Maximum velocities begun in the peace and warmth of my consulting-room continued unaltered when taken for a ride, and others begun during a round of visits continued unaltered when brought home to rest. True, I never compared the behaviour of a sample of blood taken to market with that of its brother who stayed at home. I hadn't the time or petrol for experiment. But even had I found some disparity between them, it wouldn't have worried me; for I place far more reliance on the trend of serial readings in any case than upon any single reading.

Dr. Della Vida, usually so accurate, has slipped up in one of his statements (Nov. 14, p. 591). When 4 parts of blood are diluted with 1 part of citrate, the original undiluted blood would be 25% "stronger" than the diluted sample; for five of any object is 25% and *not* 20% more than four of any object. I myself discovered this only quite recently, but among mathematicians it appears to have been known for some time.

No extravagant claims for the sedimentin index have appeared in print—yet (although some are on their way). Its wholesale condemnation by Drs. Edwards, Penman, and Cutbill (Nov. 14, p. 591) would therefore appear a trifle proleptic. This attitude of mind is not without glorious precedent, however. The White Queen screamed loudly before the brooch flew open and pricked her; and the King of Hearts, unless my memory is at fault, was all in favour of verdict and sentence before hearing the evidence. One gathers from their letter that they have failed to gain satisfaction from the sedimentin index; and I cannot help feeling that they are wise in sticking to the simplicities of the Westergren technique, which is, after all, better than nothing. Half a moment, though—is it as simple as all that, involving as it apparently does the use of a constant-temperature chamber? That wouldn't suit me, I'm afraid, nor many other practitioners similarly ill equipped.—I am, etc.,

Hartford, Cheshire. GEORGE DAY.

Obituary

J. G. McCUTCHEON, M.B., Ch.B.

Scottish members of the Association, as well as many of their English colleagues, will learn with deep regret of the death of Dr. J. G. McCutcheon of Glasgow. He had for some time been in indifferent health, but he was taken seriously ill while returning from Blackpool to Scotland, and died in a hotel at Carlisle on Nov. 22. Dr. McCutcheon, who attended the recent Annual Representative Meeting, was to his great pride and pleasure re-elected after an interval of thirteen years to the Central Council of the B.M.A. He was previously a member of Council for five years, and he had rendered long and conspicuous service on many committees, especially the Insurance Acts Committee, the old Medico-Political and Parliamentary Committee, and the Central War Emergency Committee, of which he was a member for ten years. He was also a prominent member of the Scottish Committee and had been its chairman. In 1933-4 he was chairman of the Glasgow Division, and in 1936-7 president of the Glasgow and West of Scotland Branch, of which for several years he had been honorary secretary. He was also deputy chairman of the Scottish Central Medical War Committee.

Joseph Glaister McCutcheon, a native of Lanark, was born in October, 1880. In the Boer War he served with the Scots Greys, and after his return to medical study graduated M.B., Ch.B. of Glasgow in 1908. For many years he carried on a large practice in the Townhead district of Glasgow, and later in the West End. During the last war he served with the R.A.M.C. in France and reached the rank of lieut.-colonel. For a number of years he was a member of the Glasgow Corporation; he was also a justice of the peace, and in 1937 was appointed deputy lieutenant for the City of Glasgow. He was chairman of his Panel Committee, chairman of the Medical and Dental Defence Union of Scotland, and a member of the Scottish Blood Transfusion Council. Recently he had been made a medical referee under the Ministry of Pensions.

McCutcheon will be remembered in Association meetings for his interventions in debate, always marked by vigour and good sense, and often by pawky humour. His last speech in London was in praise of health centres and group practice, and he said how much he and his family would look forward, when that came about, to living in a small private house and saving the carpets and the furniture! A genuine spirit of kindliness shone in him, and a love of fun twinkled in his rugged features. He will be greatly missed.

J. L. writes:

The sudden and tragic death of Joe McCutcheon has come as a great shock to his intimate friends, and he had many such. Though poor health, following on serious illness a few years ago, had compelled him to retire from general practice, he had yet been able to undertake work under the Ministry of Pensions, and there was nothing to indicate that his end might be so near. If such were known to him, it was characteristic of the man not to share the knowledge with others. I have enjoyed his intimate friendship for many years. The acquaintance began with a casual meeting on an embarkation wharf in August, 1914, when Capt McCutcheon, R.A.M.C, Special Reserve, as he was then, was attached to a field ambulance of the B.E.F. By the curious chances of war, we were fated subsequently to be often thrown together, first when I was attached later to the same field ambulance. After nearly a year in that unit Joe was transferred to the Home Establishment and was appointed to the medical charge of the Household Battalion, which he accompanied over-seas. Once again fate brought us together and, from personal acquaintance with the officers of that regiment, I learned of the very high regard in which Joe was held and of the great confidence reposed in him by all ranks; the expression "white man," used of him by one of the officers, perhaps aptly describes their regard. After some months he was transferred once more, and later was appointed D.A.D.M S. of the Division, wit the rank of major. In this position his ability, tact, and cheerful ness made him *persona grata* with all. His final appointment a lieut.-colonel commanding a field ambulance in the same Divisio maintained our close association up to, and after, the cessation o hostilities.

In his home life Joe was the devoted husband and ideal fathe But to the burden of his own poor health there was lately adde distress and concern occasioned by his wife's severe and painf illness, so bravely borne by her. In this, perhaps more than i anything else, was displayed the most lovable aspect of his characte while his indomitable cheerfulness was both an encouragement t her and a support to himself. Joe was a man of high ideals and strong sense of duty. Combined with these were a remarkable powe of understanding others, an infinite capacity for taking pains, an an unlimited kindliness of heart. Consideration of self would hav been his last thought, and nothing was too great a trouble if h could be of help to others

EDGAR HAYDON, M.B.

Dr. Edgar Haydon, who died at Newton Abbot, Devonshir on Nov. 16, was in his 84th year. For 55 of them he was member of the B.M.A., and in 1922-3 president of the South Western Branch. He graduated M.B., C.M. with honours a Glasgow in 1881, and held house appointments at the Glasgo Western Infirmary.

Quite apart from his professional practice (writes a colleagu few men have won the affection of a community to a greater exten than Dr. Haydon. He radiated friendliness and encouragemen towards everybody and gave himself and his substance to all goo works, notably the growth and development of Newton Abbo Hospital; indeed, its whole history from the smallest beginnings i private rooms to its present commodious and up-to-date buildin is epitomized in Dr. Haydon's life. He sponsored appeals fro public and private sources that produced thousands of pounds th the public might have the best possible treatment on their doorstep Before the last war he secured over £4,000 (a large sum for thos days), which purchased radium for the treatment of malignan disease. The war over, the need for further building extension aros and Dr. Haydon went boldly out for £16,000, which was forthcomin in less than two years. He found time, too, for much public work and served on the Newton Abbot Urban Council for some years He was a prominent Freemason, and among his honours he wa P M. Devon Lodge 1138 in 1905 and held the rank of P.P.J.G.W He was thrice president of the local Rotary Club, and for years o the Y.M.C.A. In a country area it was natural, too, that hi interest should be linked to agriculture, and in 1923 he becam chairman of Devon Agricultural Show Committee. It is difficul to find in the district any aspect of community life that he did no touch in generous and practical ways.

Another colleague writes: The name of Haydon is familiar al over this countryside and beyond, and Edgar Haydon was its mos conspicuous representative. For his kindly sympathy and medica skill he was trusted and honoured by all sorts and conditions o men, rich and poor alike. In a way he was a typical family doctor He came to the town as a young university graduate and succeede his brother, who died soon after. He took up with enthusiasm th medical and public life of the town and neighbourhood. From it small beginnings the Newton Abbot Hospital was really his chief life work; and he had a marvellous gift for enlisting the help of ric and poor in its progress The response of all classes to it needs has been due more to him than to anyone else. He wa undaunted by difficulties that would have discouraged many men and was full of resource, determination, and courage. The las months of his life were clouded by the fact that his only survivin son, Brigadier C. Haydon, was reported to be a prisoner of war His loss will be felt by his colleagues and friends for many year to come.

Mr W. SAMPSON HANDLEY writes:

In the country towns of England are often to be found practitioners who, by force of character and by long and efficient service to their patients, have become little kings in their own district, known and trusted by everyone. Such a one was Edgar Haydon. The son of a Devon doctor, he had the inestimable advantage of a country upbringing As a boy he roamed over Dartmoor and acquired that love of the moor and of horses, and that keen appreciation of Devon character and humour, which in later years gave him the key to so many hearts. His own forebears came from Cornwall, and it was perhaps from some adventurous sailor with his eyes fixed on the horizon that he inherited his wide outlook over the fields of medicine, and the spirit of exploration that to his latest days made him receptive of new methods of treatment

About 1882 he settled in Newton Abbot, and to that town and district he gave sixty years of strenuous service, only terminated a fortnight before his death In his earlier years he had medical charge of the local infirmary, and he used to attribute his success in practice to the recommendations of his Poor Law patients. It was perhaps due equally to the persistence with which, through the years, he pursued his postgraduate education by constant visits to London hospitals, and especially to the Middlesex Hospital, but most of all to his kindly and breezy personality and to his clinical acumen. He became surgeon to the Newton Abbot Cottage Hospital, and it is largely owing to his initiative that it has become an important general hospital. He equipped a new *x*-ray department at his own expense. Impressed with the value of radium for the treatment of cancer he, more than twenty years ago, collected a fund for its purchase, which gave to Newton Abbot the largest stock of radium, for its size, of any town in England. Thus equipped, the Newton Abbot Hospital, mainly through Haydon, has done valuable pioneer work in the use of radium by implantation, attracting cases from a wide district. When the present war began he had just retired from active practice, but upon the calling up of one of his partners he returned to work and seemed for a time to become a younger man, though he was then over 80. More recently acute anxiety about the fate of his only surviving son, a distinguished soldier, after the fall of Tobruk, aged him rapidly. Three of his sons died during the last war, two of them on active service.

Haydon's work did not receive the public recognition it well deserved, nor did he seek it. His house possessed one of the most beautiful gardens, for its size, in England, and is surrounded by a high granite wall within which many rare shrubs flourish. The view extends to his beloved Hey Tor. In this happy setting he passed his useful life, and he has well earned his rest. He was twice married, and leaves a widow to mourn him.

Dr. **ARTHUR BIRT** died at Halifax, Nova Scotia, on Nov. 19. He was born on Dec. 31, 1864, and was educated at Edinburgh Collegiate School, where he won the gold medal and was Dux of the school. He graduated M.B., C.M. at the University of Edinburgh in 1887 with distinction, and was house-physician at the Edinburgh Royal Infirmary. After serving five years as deputy superintendent at the Durham County Asylum he settled in Nova Scotia, where he became well known as a consulting physician, and published numerous articles in the Canadian medical journals. He proceeded M.D.Ed. with honours in 1898, and was elected a Fellow of the Royal College of Physicians of Canada in 1931.

The Services

The King has approved the award of the R.N.V.R. Officers' Decoration to Surg. Cmdrs. E. A. Gerrard and J. L. Cox and Acting Surg. Cmdr. E. I. Puddy, R.N.V.R.

CASUALTIES IN THE MEDICAL SERVICES

Temp. Surg. Lieut. **DOUGLAS JAMES NAUGHTON**, R.N.V.R., is included as "missing, believed killed" in an Admiralty Casualty List published on Nov. 19. He was born on May 15, 1913, and was educated at Trinity College, Dublin, where he graduated M.B., B.Ch., B.A.O. in 1941. He held a house post at Hull Royal Infirmary before entering the R.N.V.R. this year.

Surg. Lieut. **ALASTAIR BAIRD KENNEDY**, R.N.V.R., is reported "missing, presumed killed" on active service. He was born on Aug. 3, 1906, the only son of Mr. and Mrs. A. A. Kennedy of Seaton, Devon, and qualified L.M.S.S.A. in 1940. After holding a resident post at Wellhouse Hospital, Barnet, he entered the R.N.V.R. last January. He leaves a widow.

Lieut.-Col. **DELVINE BELL**, M.C., R.A.M.C., died at Netley on Nov. 3. He was born on Oct. 22, 1888, and was educated at the University of Edinburgh, where he graduated M.B., Ch.B. in 1911. After serving as resident surgical officer at the Schiff Home and as house-surgeon at the Swansea General and Eye Hospital he entered the R.A.M.C. as lieut. in Oct., 1914. He became lieut.-col. in 1938. He served in the war of 1914-18, was twice mentioned in dispatches, and was awarded the M.C. He had recently been stationed at Cairo.

War Subs. Capt. **JOHN WALLS GIBSON**, R.A.M.C., was killed in action in the Middle East in November. He was born on April 21, 1917, the only son of Mr. and Mrs. Andrew Gibson of Uphall, Broxburn; West Lothian, and was educated at the University of Edinburgh, where he graduated M.B., Ch.B. in 1939. After working as an assistant to a Leeds firm of doctors he entered the R.A.M.C. as temp. lieut. He was a member of the B.M.A.

Prisoners of War.—War Subs. Capt. J. K. Drucquer, R.A.M.C., War Subs. Capt. J. H. McLaughlin, R.A.M.C., War Subs. Capt. F. J. Murray, R.A.M.C., War Subs Capt. R. J. S. Walker, R.A.M.C.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

At a Congregation held on Nov. 20 the degrees of M.B., B.Chir were conferred by proxy on J. C. N. Westwood and W. K. S Moore.

UNIVERSITY OF EDINBURGH

At the last meeting of the University Court it was agreed, on the recommendation of the Faculty of Medicine and the Senatus, to invite Prof. E. D. Adrian, O.M., M.D., F.R.S., to deliver the Sharpey-Schafer memorial lecture for 1943.

UNIVERSITY OF GLASGOW

The University Court has accepted an offer from Mr. Fred H. Young, a Glasgow carpet manufacturer, of a sum of £22,000 to endow a lectureship in orthopaedics within the department of the Regius Professor of Surgery. At the request of the donor and with a view to providing clinical facilities, the Court has invited the co-operation of the managers of the Western Infirmary and, at least during the war, of the Department of Health for Scotland. The lectureship will be associated with the post of orthopaedic surgeon (with charge of the out-patient casualty department) at the Western Infirmary and with the post of visiting orthopaedic surgeon to a country emergency hospital in the West of Scotland.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Annual Meeting of Fellows and Members

The annual meeting of Fellows and Members of the Royal College of Surgeons was held at Lincoln's Inn Fields on Nov 19. The President, Sir Alfred Webb-Johnson, presented the general report of the Council for 1942. In doing so he referred to a marked quickening of interest on the part of the Fellows and Members in the doings of the College. Many of the concerns now occupying the Council might very largely affect the future of the younger Fellows and Members. In participating in the work of the Medical Planning Commission particularly the Council was desirous of gathering the feeling of the younger surgeons.

The President went on to say that it had been decided that the time had come when changes were needed in the College examinations. The Council had applied for permission to alter the by-laws so as to make the Primary Fellowship examination postgraduate and to add pathology as one of the subjects. A hardship had been experienced in respect to the Final Fellowship examination, whereby many candidates from over-seas could not be admitted to the examination until four years after qualification, or, to avoid this period of waiting, they must take the examinations for the L.R.C.P., M.R.C.S. diplomas, though they were already in possession of university degrees. It had therefore been decided to seek an alteration whereby there would be required from such candidates for the Final examination evidence of training and experience which the Council might from time to time deem necessary in order to maintain the high standard of the Fellowship. Another innovation was the establishment of a research chair in ophthalmology. Finally, he referred to the working together of the three Royal Colleges There was already a standing joint committee, and the question of post-war building had been considered. Each of the Colleges had shown a desire that all three should be housed on one site, but although sites, including Lincoln's Inn Fields, had been considered, no conclusion had yet been reached. It must be better for all three to work together than to be in different parts of London. One of the Colleges had asked for the drawing up of criteria concerning the training and status of consultants, and this had been done.

In some brief discussion following the President's remarks, Mr. R. M. Handfield-Jones referred to a certain apathy which had existed among Fellows concerning College affairs. In the sister College there was a Comitia which was open to Fellows and at which the Council was able to gather their opinions on matters of internal and external policy. It would be a good thing to elicit the opinion of the general body of Fellows on matters of importance, and meetings for this purpose, while having no status and being quite informal, might strengthen the hands of the Council. Mr. E. A. Crook thanked the President and Council for the anxiety they had shown to learn the feelings of the younger surgeons. Mr. D. H Patey spoke of the reconstruction of the museum, and suggested that the emphasis in the re-formed collection should be on quality rather than on quantity. The amount of material in the past had been a weakness rather than a strength.

The President, in replying, said that strong reasons would certainly have to be forthcoming if the College consented to move from Lincoln's Inn Fields. It had still about £200,000 worth of building standing, which was not adaptable to any other purpose.

The usual resolution calling for representation of Members on the Council was not taken at this meeting, because since the war there has been no possibility of obtaining any change in the Charter of the College.

Medical Notes in Parliament

Acting Rank in the Army

Sir J. Grigg, replying to questions on the subject of acting and temporary rank in the Army, said he had reviewed the rules under which officers had been required to relinquish temporary rank on ceasing to perform the duties for which the rank was granted. He had come to the conclusion that there were good grounds for giving the holder of temporary rank, which might have been held for long periods, a greater degree of security in his rank. In future an officer holding temporary rank would be permitted to retain it while on a course of instruction. He would retain it during the interval between being posted away from one unit and joining his new unit, provided he was fit and available for duty during the whole period and any delay in his joining his new unit was due solely to the exigencies of the Service; this would cover the voyage period in the case of officers ordered over-seas. In addition officers would be permitted to retain temporary rank while absent sick up to a period of two months (provided that the sickness was not their fault), and, as previously, for three months if wounded in action.

Venereal Disease

On Nov. 17 Mr. Boothby asked the Secretary of State for Scotland what steps were being taken to combat the menace of venereal disease by means of propaganda designed to encourage preventive measures and to secure immediate treatment in cases of infection. Mr. Johnston said he hoped to issue to local health authorities this week a circular reminding them of the continuing need for enlightenment of the public about venereal disease and urging them to consider at once an expansion of their arrangements in this respect.

Dr. Summerskill asked if the Minister was aware that the Government had introduced a regulation on this subject which, from a medical point of view, was so limited in character that it would be quite ineffective in stamping out venereal disease. Mr. Johnston: That regulation has been drafted on the advice of our skilled medical officers.

On Nov. 17 Major Lloyd asked the Secretary of State for Scotland whether, to combat the increase in venereal disease in certain areas in Scotland, he would take immediate steps to make this disease compulsorily notifiable, empowering local authorities to follow up and treat the victims of the disease. Mr. Johnston said that the first part of the question raised highly controversial issues, but powers had been taken by Defence Regulation under which medical officers of health might require any person who had been reported by two separate patients as the source of infection to undergo medical examination and any necessary treatment, and to remain under treatment until certified free from infection. He was bringing these powers to the attention of local health authorities and their medical officers of health. The result of the operation of the Regulation would be kept under regular review.

Industrial Medicine

Sir David Munro, addressing the Conservative Health and Housing Committee on Nov. 17, referred to what he termed the charter of the works medical service given by Mr. Bevin in his Order of July, 1940, in which it was laid down that factory managements were to engage doctors and/or nurses in circumstances recommended by the Factory Department. Not all firms could engage a whole-time doctor, but the larger number of part-time doctors thus drawn in would promote the education—badly needed—of general practitioners in occupational disease. With illustrations from the Royal Ordnance Factory Medical Service, Sir David indicated what a State service might do in the selection of operatives for their suitable occupations, in improving their health and efficiency at work, and in rehabilitating them after injury or illness. He envisaged an institute of industrial medicine, at which, for instance, all toxic substances should be examined for their harmful effects before being taken into industrial use, and a diploma of industrial medicine, perhaps even a membership and fellowship under the aegis of such a body as the Royal College of Physicians. The medical services were part of welfare, and there should be in every factory a fusion between production, management, and health and welfare services. All were a function of management. This was achieved at the Ministry of Supply by a Welfare Board.

Pensions Appeal Tribunals

The Debate on the Address was resumed in the House of Commons on Nov. 18 and succeeding days.

Major Milner said the delay in setting up pensions appeal tribunals was inexcusable. He understood that if the Medical Personnel Priority Committee were directed by the Governme it could find the doctors for the staffing of these tribunals- a matter of 50. Sir Stafford Cripps replied that t desirability of these tribunals was not an issue. The so question was whether at present it was possible to constitu them. All the suggestions for temporary or alternative pr cedure had not been approved by the organizations representin ex-Service men. The Ministry of Pensions found great dif culty in getting sufficient medical men for its current need Those coming forward were not suitable, or those suitab were not sufficient. Not the Central Medical War Committe nor the Services Departments, nor the Priority Committee cou provide a sufficient number of highly qualified medical men carry on the purposes of these tribunals. These bodies had bee asked, and that was their answer.

Dr. Haden Guest interposed to say the chairman of t Priority Committee had told him he might say this was not s Sir Stafford said that, granted priority, medical men could taken away from the Services, but to get medical personnel sufficiently high standard for final tribunals was, at the prese time, impossible.

War Workers and Hours of Work

Mr. Brown told Sir Robert Young on Nov. 19 that he ha seen a Press report of the proceedings of the Annual Pan Conference, and particularly the statements made by medic men regarding the health conditions of war workers, and alleg tions of physical and mental exhaustion as the result excessive hours of work. The conference had not made a reference to him on the matter. Should it do so, he would ce tainly consider what action on his part appeared to be called fo

Nutritional Anaemia

Replying to Dr. Summerskill on Nov. 19, Mr. Brown sa his attention had been called to an article in the medical pre which stated that evidence of nutritional anaemia had bee found among certain groups of women and young childre He had therefore arranged for iron preparations to be availab in all day and residential nurseries and in emergency materni homes. The majority of welfare authorities already provide similar preparations at their centres for expectant mothers an young children found to require them.

Panel Capitation Fee

Sir Leonard Lyle asked on Nov. 19 if Mr. Brown kne that since the start of the war the general body of insuranc practitioners had tried to secure an increase in the capitatio fees adequate to enable them to meet the extra cost of wartim conditions and the increased work involved, the increase su gested being 2s., of which only 9d. was approved; and whethe he had reached a decision on the representations made to hi on this subject by the Insurance Acts Committee of the B.M. Mr. Brown said he had received representations from the com mittee to this effect. He had agreed that from the beginnin of this year the capitation fee should be increased from 9s. 9s. 9d. a year to meet the increase in practice expenses and th loss of private fees from the new class of insured persons. H had considered the request made this year for a further increas and on Oct. 17 he informed the committee that he was no able to accede to it.

Medical Advisory Committee

Sir Francis Fremantle on Nov. 26 asked what steps th Minister of Health was taking to keep in touch with representa tive medical opinion in regard to the planning of the future o health services. Miss Horsbrugh said Mr. Brown had for som time felt the need for associating with the work of the Ministr of Health a representative body of medical men and wome engaged mainly in the clinical practice of their profession. H had therefore set up a Medical Advisory Committee whos terms of reference were to advise him on the medical aspect of problems relating to the health of the people. [The name of the members of the committee are published on page 670.

Nurses' Eligibility for Workmen's Compensation.—On Nov. 1 Mr. William Brown asked the Home Secretary whether he woul take steps to ensure that the nursing profession came within th scope of the Workmen's Compensation Acts. Mr Peake replie that Mr. Brown was under a misapprehension in thinking that th nursing profession as such was outside the scope of the Act. I any individual case it depended on whether the nurse worked unde a contract of service, and from a decision of the Court of Appeal i 1938 it appeared that, generally speaking, nurses in hospitals an similar institutions came within the Act.

Committee on Medical Schools.—On Nov. 24 Mr. Mander aske the Minister of Health the position with regard to the Committe on Medical Schools which was considering the desirability of increas ing the facilities for women to study in medical schools in London and when a report was expected. Miss Horsbrugh replied that sh could not give a date for the report, but the issues involved were o first-rate importance and would demand some time for examination

No. 45

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Nov. 14.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London) (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1942					1941 (Corresponding Week)

Rate per 1,000 total births (including stillborn)			45					44		

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes paratyphoid A and B for Northern Ireland.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week a sharp rise occurred in the incidence of measles 347, whooping-cough 190, scarlet fever 144, and diphtheria 59. Cerebrospinal fever, with a drop of 15 in notifications, is now at the lowest level since 1939.

Yorks West Riding had the largest rise in the notifications of scarlet fever 71, and of diphtheria 31; while Lancashire, with 23 more cases than last week, had the greatest increase in whooping-cough.

The notifications of dysentery were 6 more than last week. Outbreaks were reported during the week from Yorks West Riding (Leeds C.B. 18) and in Hertfordshire, where 11 cases were recorded in the adjacent rural districts of Berkhamsted and Watford; 21 more cases were recorded in the outbreak in Yorks North Riding, Middlesbrough C.B. In London the cases rose from 14 to 21, and in Wales from 8 to 14. Other important centres of infection were Durham 12, and Surrey 10.

In *Scotland* a rise again occurred in the incidence of measles, 30 cases, while a fall was registered for diphtheria, 46, and for scarlet fever, 61. Notifications of measles were high in the burghs of Dundee and Kirkcaldy—in the former rising from 47 to 104, and in the latter from 29 to 56.

In *Eire* there were a few more cases of poliomyelitis; during the past ten weeks 226 cases have been notified. The outbreak of typhus in Galway, 13 cases, has resulted in 1 death. The increasing incidence of scabies is causing concern to the local authorities.

Small-pox

No fresh cases have been confirmed in Edinburgh during the last week. At present there are 20 patients and 1 under observation in the small-pox wards. No further cases have been reported from Cowdenbeath. A suspected case in Perth was not confirmed, but small-pox has appeared in a new area—the case of a young male in Inverurie, Aberdeenshire, having been reported.

Measles

The notifications of measles in England and Wales are higher than they have been for over a year. The largest increases recorded during the week under review were those of Yorks West Riding 282, and Lancashire 75. These two counties had almost half—3,840 out of 7,731—of the total cases in the country, and their recent experience has influenced to a considerable extent the general trend of this disease. Since the beginning of September the weekly notifications have been more than doubled in Lancashire, and a six-fold increase has occurred in Yorks West Riding. Particularly severe outbreaks have been recorded in some of the county boroughs of these counties. The largest totals during the week reviewed were: Yorks West Riding, Bradford C.B. 505, Leeds C.B. 386, Huddersfield C.B. 167, Sheffield C.B. 120; Lancashire, Manchester C.B. 282, St. Helens C.B. 206, Blackpool C.B. 146.

Returns for the Week Ending November 21

The returns of infectious diseases in England and Wales included the following: scarlet fever 2,914, whooping-cough 1,246, diphtheria 1,001, measles 8,816, acute pneumonia 645, cerebrospinal fever 68, dysentery 117, paratyphoid 5, typhoid 6

Medical News

Dr. Donald Hunter, F.R.C.P., will deliver the Finlayson Memorial Lecture on "Generalized Diseases of the Skeleton" in the hall of the Royal Faculty of Physicians and Surgeons, 242, St. Vincent Street, Glasgow, on Wednesday, Dec. 9, at 4 p.m

At a meeting of the Section of Therapeutics of the Royal Society of Medicine on Dec. 8, at 2.30 p.m, a discussion on "The Aetiology of Erythroblastosis Foetalis on Certain Haemolytic Transfusion Reactions, with Special Reference to the Rh Factor" will be opened by Drs. P. L. Mollison and G. L. Taylor.

The last lecture in this year's autumn programme of Chadwick Public Lectures will be given on Tuesday, Dec. 8, at 2.30 p.m., at the Royal Society of Tropical Medicine, 26, Portland Place, W., by Dr. W. Norwood East on "The Differentiation, Prevention, and Treatment of Anti-social Behaviour Disorders." Admission is free; tickets are not required.

A meeting of the Pharmaceutical Society will be held at Friends House, Euston Road, N.W., on Thursday, Dec. 10, at 2.30 p.m., when Dr. R. Melville will deliver a lecture on "Medicinal Indigenous Plants."

On Nov. 25 Mr. Arthur W. Down celebrated his 90th birthday. Throughout its existence he has been the guiding spirit of Down Bros. Ltd., surgical instrument manufacturers.

An appointments bureau for out-patients, open from 9 a.m. to 5 p.m., came into operation at the Charing Cross Hospital on Dec. 1. Doctors are invited to telephone or write for appointments Members of the public also may write for an appointment or apply personally at the hospital. The creation of this bureau is in line with the general policy of the big London general hospitals, which are using the appointments system in an effort to save the time of patients and to enable the hospital authorities to organize a schedule of working.

The Council of the National Association for the Prevention of Tuberculosis passed the following resolution on Oct. 19: "The Government declaration on tuberculosis is a great step forward which all interested in the eradication of this disease will most heartily welcome. The National Association desires also to congratulate the Minister of Health and the Secretary of State for Scotland on having brought forward this great reform and offers its whole-hearted co-operation in the practical working of the scheme. The National Association is taking the earliest possible opportunity of obtaining further information about the scheme."

Dr. B A. Thomas (Gray's Inn) was called to the Bar on Nov. 17.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent, London;* SECRETARY, *Medisecra Westcent, London*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Sulphonamides for Leukaemia?

Dr. J. HARTON RAYNER writes to ask if drugs of the sulphonamide group have been used with any effect in the leukaemias by reason of their known leucopenic action.

Intractable Urticaria

C. B. suggests that J. R. (Nov 28, p. 654) should minutely investigate the possibility of the condition being due to dental sepsis or infection of nasal sinuses. The association is not unusual.

First-aid Treatment of Wounds

Dr. CYRIL GOULD (Corps Surgeon, Luton Corps, St. John Ambulance Brigade) writes: In reply to J. R. L. (Oct. 31, p. 534), first aid is not treatment, but *assistance* rendered at the time of the emergency with such material as may be available until medical aid is procurable. Candidates for the B.R.C. or St. John Ambulance Association exams are, or should be, examined on the manuals, and therefore lecturers should keep strictly to the books. Having passed their first-aid exam, personnel of first-aid posts, etc., may be taught the particular treatment of wounds, burns, etc., the M.O. i/c prefers.

Income Tax

Consultant. Entertainment Expenses

XX has been assessed as a consultant for some years and has been allowed to deduct an estimated amount (15s. per week) for expenditure incurred in entertaining general practitioners at his house in order to maintain the personal contacts which he regards as necessary for his practice. A new inspector of taxes now says that he knows of no authority for the deduction and proposes to discontinue it.

*** The question of entertainment expenses is a difficult one. To be allowable expenses must come within the description "money wholly and exclusively laid out or expended for the purposes of the . . . profession." In applying this rule some bodies of Commissioners take a more stringent line than others. Broadly speaking, such allowances are made, on reasonable evidence being produced, in the case of ordinary business people, or commercial travellers, but some of the more important bodies of Commissioners refuse to make such deductions in the case of professions—e.g. barristers, or even stockbrokers. The ground of refusal is usually that the expense is too indirect to justify it being charged against professional profits. If XX feels satisfie as to his facts and is prepared to support his claim by oral testimony, we suggest that he should appeal, preferably to the Specia Commissioners rather than to the local Commissioners.

LETTERS, NOTES, ETC.

Unusual Skin Sensitivity

Dr. ZIKMUND WINTER (London, W.C.1) writes: Dr. Allan Bigham' report (Nov. 14, p. 578) of a recent case of abnormal skin sensitivity is of great interest. It seems to me the only appropriat explanation that could be given is the pressure with stimuli o different temperature and not the negative sensitivity to gold. Hi observation proves that the mechanical stimulus of pressure i certain sensitive subjects does not produce the typical tripl response (Lewis) if its temperature is lower than the skin. On must conclude that in areas where the wedding ring had bee pressed against the skin the liberation of "H substance" did nc take place; consequently the complex vascular response wit vesicle formation failed to appear This patient apparentl belonged to the group of subjects where pressure elicits the tripl response only if applied with stimuli of body temperature. It i very difficult to assume a negative sensitivity of skin to gold, bu easier the negative sensitivity to pressure with cold objects.

Control of Venereal Disease: Correction

In our leading article on Nov. 21 (p. 611) it was said that "th arguments adduced by the British commission against compulsor measures were that they (1) may induce the infected to conce the disease from fear of exposure, (2) are not easy to apply i such a densely populated country as this on account of the diff culty in tracing those who try to evade the law, (3) may open th way to blackmail, and (4) are not consonant with the British ide of the liberty of the subject." The arguments thus quoted wer not in fact put forward by the British commission of experts sen to Holland and Scandinavia in 1937 by the Minister of Healtl but appeared in some preliminary remarks in our issue of June 11 1938, before summarizing the report of that commission.

MEDICINE 100 YEARS AGO

Extract from a leading article in the *Provincial Medical Journa* of Dec. 3, 1842:

"The condition of the dwelling-houses of the poorer classe whether as regards their internal economy or external situation forms a most important object of inquiry to the philanthropist an the physician. When we reflect upon the influence which the varying circumstances of site and elevation, and exposure to air an moisture, must exercise upon the health and comfort of the artisa and the cottager—when it is considered that the free circulation o air, the access of light, and protection from cold and damp, an from noxious exhalations and impurities, whether of the ai respired or the water employed in the various branches of domesti economy, are important to all, but doubly so to those who are fron poverty deprived of the means of guarding against many of th inlets to disease—there is little need of labored argument to shov the importance of such inquiries. No reflecting person, who i conversant with the habits, and, from personal inspection, familia with the dwellings of the working population of this country, wil hesitate to admit that there is great room for improvement in both The site of the houses of the manufacturing portion of our population, in particular, has been too generally chosen with reference t the one only view of proximity to the factory, regardless alike o the comfort and the health of the inmates. These houses are fo the most part situated in the midst of the noxious effluvia generate by the various processes carried on at the manufactory, because i is considered advantageous that the workman should be near a hand; they are crowded into a small space, the value of the groun not allowing of sufficient room for much attention to ventilation or to the admission of light. The banks of rivers and canals bein desirable situations for factories, as well on account of the suppl of water for working the machinery, as for the convenience o transporting the products of labor, the ground is very frequentl swampy, and drainage, or other means of providing again accumulation of dirt and filth, rarely enters into the contemplatio either of owner or occupier of the miserable tenements with whic such places abound. Can it then be a matter of surprise that th population reared under such circumstances should be squalid stinted in growth, scrofulous in constitution, and careless of thos decencies of every-day life in the absence of which there is no chec to the development of vicious tastes, no impediment to the indulgence of vicious appetites? Can it be a matter of surprise that i such places scrofula, pulmonic affections, and rheumatism ar endemic, and that fever and scarlatina, cholera, diarrhoea, an dysentery are frequent in their visitations and assume their mos fearful and fatal characters?"

THE PAIN PATHWAYS IN MIGRAINE

BY

G. F. ROWBOTHAM, B.Sc., F.R.C.S.

Surgeon-in-Charge, Neurosurgical Service, Newcastle-upon-Tyne; E.M.S. Consultant in Neurosurgery, Region 1

The term "migraine," the derivation of which has been stated by Kinnier Wilson (1940),* is probably best used in a clinical sense to denote a particular variety of headache and not with a pathological implication suggesting that the physio-pathological processes which cause the head pains are known. The characteristic features of migrainous headaches are unilaterality and periodicity, the pain starting slowly, reaching a peak of severity, continuing at this degree of severity for a varying period of time, and then slowly receding. Most typically, the headache is associated with black spots in front of the eyes, with flashes of light, or with formed and coloured visual hallucinations. There are, of course, many variations. In particular, the pains may be mild or severe: they may or may not be accompanied by visual phenomena: they are often bilateral, and they may radiate into the face or neck.

Headaches of a migrainous type may be divided into two distinct groups: (i) those associated with a demonstrable pathological lesion, such as a cerebral aneurysm; (ii) those which cannot be accounted for by local cerebral change or by gross metabolic disturbance. It is with the latter group only that this communication is concerned.

In migraine, as in other painful conditions, before treatment can be instituted the clinician must have some conception of the nature of the disturbance which initiates the pain cycle, of the site at which the painful impulses arise, and of the anatomical pathways by which painful impulses are conveyed to the brain.

First let us consider the site at which the painful impulse arises. This may be in the brain tissue itself or in one of those structures of the head—the scalp, periosteum, meningeal vessels, the large arteries at the base of the brain, and the dural sinuses—which are known to be capable of reacting in a painful way to an adequate stimulus (Penfield, 1940). From all these possibilities—and, of course, there may be others unknown—the pain of migraine is believed to arise in the arteries of the scalp and dura mater. The reasons for this belief are as follows:

(1) The walls of large blood vessels have been proved to be painful, and some to possess local sign. When operating under local anaesthesia, crushing of the trunk or of the large branches of the meningeal artery will cause extreme discomfort, and the patient will be able at least to "lateralize" the pain.

(2) Spasm of a large artery will lead to pain. Once when dissecting in the neck under local anaesthesia, in order to carry out cerebral angiography, the internal and external carotid arteries went into extreme spasm. Immediately severe pains were complained of in the same side of the head and face, and the patient slowly developed a contralateral hemiplegia, which equally slowly receded.

(3) Extreme dilatation of an artery will lead to pain. This can be proved by isolating a segment of a large artery in the scalp and by injecting saline forcibly into its lumen.

(4) The vascular changes which accompany migraine. The skin of the forehead in an attack is often deadly pale, the temporal arteries are distended, and there may be associated neurological signs which can only be accounted for by cerebral ischaemia. Occasionally a retinal vessel can be seen to be in spasm.

(5) The experiments on headaches produced by histamine (Clark, Hough, and Wolff, 1936).

(6) The relief of migraine by injections of ergotamine tartrate.

If the vascular origin of migrainous pains is accepted, then it is easy to conjecture on the essential disturbance which starts the pain cycle.

A popular theory is "neurosis of the cerebral autonomic nervous system." This postulates that there is an unstable equilibrium (Hughlings Jackson, 1931) in one or other of the central mechanisms of the autonomic nervous system, such as the hypothalamus, which reacts abnormally to some of the many stimuli that reach it from other parts of the nervous system or blood stream, thereby discharging abnormal impulses to the more peripheral parts of the sympathetic and parasympathetic nervous system (Fig. 1). This theory may explain why the so-called causes of migraine already described are legion. It will be seen, however, that the nature of the original disturbance which causes migraine and the site at which the painful impulse arises are essentially matters of speculation.

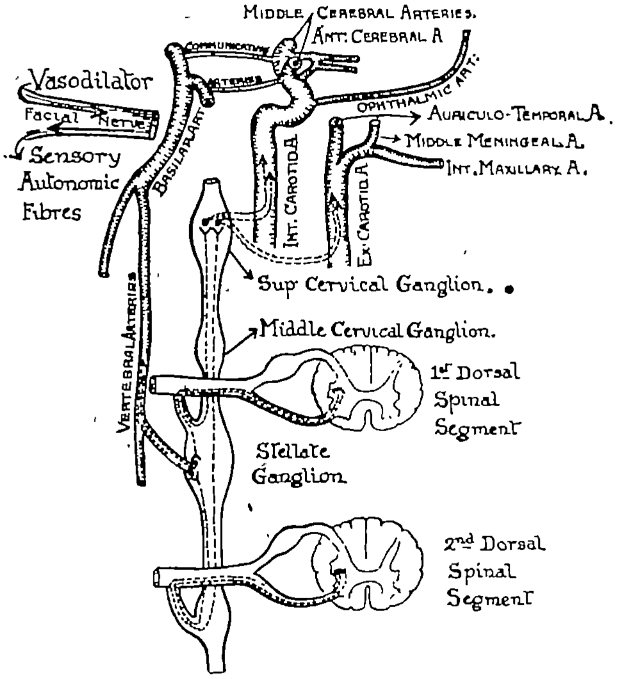

FIG. 1.—The sympathetic innervation of the blood vessels of the brain, dura, and scalp.

---

* "Migraine is derived from Galen's ἡμικρανία through L. hemicranium and L.L. hemigranea, later migranea. In England hemigranea became mygrame, myegrym, migrim, and megrim. Migraine itself is French."

The last point to be considered is the pathway by which the painful impulses are conveyed to the brain. Do these impulses pass to the brain stem by way of the known or rather by way of the described autonomic pathways or otherwise? An attempt to answer this question will be found in the following series of cases.

Case I

Mrs. J. S. reported to me at the Salford Royal Hospital on July 12, 1940, complaining of migraine which she had had for many years and for which she had received treatment by Dr. Don and Prof. Jefferson. Her pain was chiefly right-sided, but occasionally the left side was affected. Typically, it would come on suddenly in the region of the forehead, rapidly spreading to the eye and to the back of the head. Often it would travel down into the cheek but never as far as the lip. In severe attacks she would vomit and the sight in the right eye would become dim. The pain often lasted for a week or more, when she might be incapacitated for several days and be confined to bed.

On examination she proved to be a well-built little woman, aged 40, with no emotional complexes and of good average intelligence. There were no abnormal neurological signs, and special investigations failed to reveal any pathological change to account for her pain. The diagnosis of migraine, made by other competent observers, was confirmed, and later I saw her in a typical attack. She insisted that something surgical must be done to give her relief, as all kinds of medical therapy had failed. Therefore I discussed with her the possibilities of thoraco-cervical sympathectomy and trigeminal root section, but before deciding to operate persuaded her to submit to a further course of medical therapy, including injections of ergotamine tartrate. Again the recognized forms of treatment, adequately administered, failed to satisfy her.

On the afternoon of Sept. 3, 1940, I operated on her under general anaesthesia in the sitting position, and divided the upper and inner third of the right trigeminal root, through the lateral extradural approach of Frazier. At the end of the operation she was conscious, and the next morning was perfectly well and fully co-operative. The denervation was satisfactory, the anterior two-thirds of the scalp on the operated side being numb, as well as the upper part of the cheek. A Buller's shield was fixed in position to protect the insensitive cornea. The immediate result was excellent; she felt easy and confident. From the time of the operation she has not had another attack of migraine, although she does complain of tingling pains at the junction of the numb and sensitive areas in the cheek. The following is an extract of a report from Mr. Wyse, resident surgical officer of the Salford Royal Hospital, dated June 18, 1942:

"I saw Mrs. S. yesterday. She has had a very worrying time recently, having lost her mother, and she states that she would never have been able to carry on had she not had her operation. She has never had migraine since, she states; and says that the operation has been a wonderful success. She gets occasional pains in the right side of the forehead in the form of hot stabs, but these do not worry her. She has practically no pain on the left side. She feels her face a bit numb and stiff, of course, and says the cheeks swell badly at times, but she has had no trouble with the right eye."

Case II

Miss D. R., aged 25, first came to see me on Nov. 23, 1935, at my out-patient department of the Christie Hospital at the request of her general practitioner, Dr. Friedlander. She was complaining of pains in her head, which were so severe that she had been completely disabled and off work for several weeks. The pain was so bad that her doctor thought in the early stages that she might have a cerebral tumour, or an obstructive hydrocephalus due to meningeal adhesions. Typically, the pain started low in the right temple as an indefinite ache, then travelled across the eyebrow to the middle line, at which time it became exceedingly severe. She likened the pain to the sensation that might be felt if something were being driven hard into the frontal bone. At no time did she have visual hallucinations, but in some attacks felt so ill and nauseated that she would lose several pounds in weight. Occasionally she had pains on the left side of the head, but these were much less severe than those on the right and certainly were much less frequent.

Examination showed her to be a thin little woman who looked about 18 rather than her 25 years, and weighed only 6 stone. Intellectually she was well above the average. She was rather highly strung, but enjoyed life and had no psychoneurotic tendencies. Apart from a moderate degree of hyperreflexia, there were no abnormal neurological signs to point to any focus of organic disease in her brain; also special investigations revealed no abnormality. A diagnosis was made o migraine, and she was put on a further course of medica therapy, including injections of ergotamine tartrate. In May 1939, she declared that medical treatment, which I believe wa correctly administered, had not given her satisfactory relie and she asked for something further to be done. I therefor discussed with her the possibilities of fractional trigeminal roc section, alcohol injection into the Gasserian ganglion, an thoraco-cervical sympathectomy. It was decided to divide th upper fibres of the posterior trigeminal root.

On May 11, 1939, under general anaesthesia, I divided th ophthalmic fibres in the right trigeminal root and also th second division of the trigeminus at the foramen rotundum b the lateral extradural approach of Frazier (Fig. 2). A rapi

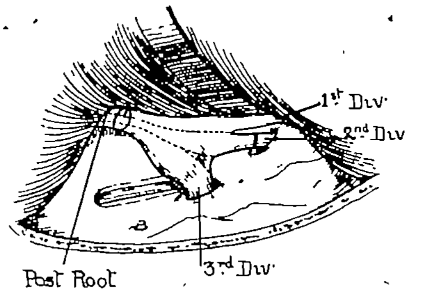

FIG. 2.—The trigeminus in the middle fossa. For the treatment of migraine usually the ophthalmic fibres only in the posterior root are divided. In some cases, however, it is also necessary to divide the second division at the foramen rotundum.

and uninterrupted recovery was made from the operation. Th trigeminal denervation was satisfactory. Anaesthesia wa present in the first and second divisions of the trigeminal fiel the third division being spared.

Since the operation, in spite of loss of sensation in the corne there has never been any suggestion of keratitis (ulceration o the cornea), and this is due to the eye remaining moist, th nerve of tear secretion—the great superficial petrosal nerve— having been spared at the time of the operation (Rowbotham 1939).

There was complete relief of pain until Sept. 20, 1939, whe at the end of a period of menstruation a pain was experience on the right side of the head (that is, the side operated on The pain was much less severe than before the operation, an lasted for a shorter time. Moreover, it was changed i character, being now described as a hot rather than as a dee pressing sensation. In spite of this recurrence of pain Miss F stated that she "was a different girl" and quite able to do he work, whereas before the operation she had been seriousl incapacitated. In Oct., 1940, she was still very satisfied wit the results of the operation. The following is the latest repo from her, dated Aug. 1, 1942:

"You will, I know, be just as pleased to hear, as I am t write, that I am quite a different and happier person fro what I was a little over three years ago, thanks to the comple relief from pain effected by the operation which yo performed."

Case III

Miss M. U., aged 48, reported to me at the Christie Hospit in April, 1939, complaining of severe pains in the right side the head, from which she had suffered periodically for thr years. In character the pain was a severe ache, and at its pea would affect the whole of the right side of the head, radiatin into the eye and upper part of the cheek. The headaches we accompanied by nausea, although she never vomited; som times she noticed black spots in front of her eyes. On ra occasions she had attacks of pain on the left side of the hea

On examination she was seen to be a thin miserable-lookin woman of an obviously neurotic disposition. Moreover, sh was a spinster, and it was suspected that the pain might b psychogenic in origin. Clinically, there were no abnorm neurological signs to point to any cerebral change to accou for her pain, and special investigations were negative.

A provisional diagnosis was made of migraine, and this w confirmed by keeping her under observation in hospita Medical therapy failed to give her any lasting relief. Wit some hesitancy I decided to sever the upper fibres of the rig trigeminal root. On April 27, 1939, under general anaesthesi I divided the ophthalmic fibres in the trigeminal root and als the second division of the trigeminus at the foramen rotundu via the lateral extradural approach of Frazier. After the opera tion she was anaesthetic in the first and second divisions of th trigeminus, the third division being spared.

The right cornea remained healthy until investigations into the problems of tear secretion were carried out. After this a keratitis developed which necessitated closure of the lids by tarsorrhaphy. For many months this woman was completely relieved of the pain in the right side of the head, but later began to complain of pains elsewhere in the body and, according to her doctor, was beginning to show distinct mental changes.

On Jan. 24, 1942, Prof. Jefferson wrote to me to say that he had seen the patient again. He told me that my operation had completely relieved the pain on the right side of the head but that obvious migrainous pains were starting on the left side. Moreover, she complained of pains elsewhere in the body.

Discussion

The possible criticism that, in my posterior root section cases, the relief of pain might be due to division of the auriculo-temporal and meningeal arteries is vitiated by the fact that injection of the Gasserian ganglion (Harris, 1936) will give relief, and this does not interfere with the blood vessels concerned. Also, division of the meningeal artery, and presumably also of the auriculo-temporal artery, in some cases of migraine has proved not to give relief (Craig, 1935). Moreover, the auriculo-temporal artery is not necessarily divided in posterior trigeminal root section, and certainly in two of my cases the large trunk of this vessel was not ligatured or diathermized. In any case, the ophthalmic artery is not involved in the lateral approach to the posterior trigeminal root, and it is along this vessel that many migrainous pains presumably arise. Finally, it is unlikely that local interference with a distal mechanism will ease pain of an extensive distribution.

If it is correct that the painful impulses in migraine do, in fact, enter the brain stem along the posterior trigeminal root, then it is still necessary to discuss how they reach the ganglion from the periphery. There are two possibilities—either they enter the ganglion from the autonomic plexus in the region of the foramen lacerum medium or they course along the ophthalmic and maxillary trunks of the trigeminus (first and second divisions). Probably the trigeminal trunks are the anatomical pathways concerned. This opinion is difficult to prove because the critical operation of section of the first and second divisions themselves in a suitable case has never been carried out, for the reason that section of the ophthalmic division (not the ophthalmic fibres in the posterior root) is a very difficult manœuvre, although it can be done (Rowbotham, 1939). In two of my cases, when the pain extended into the face, I sectioned the ophthalmic fibres only in the posterior nerve root, and the second division at the foramen rotundum, with the relief of pain. It must, however, be realized that it is impossible to know precisely how many fibres are being divided when fractional section of the posterior trigeminal root is being performed.

In one case, when a migrainous pain was confined to one side of the forehead, I divided the supra-orbital and supratrochlear nerves without dividing the supra-orbital vessels, with relief of pain. This is a very simple operation, and is worthy of trial when severe pains are localized to the forehead.

At this point it would be profitable to inquire into the results of thoraco-cervical sympathectomy in the relief of migrainous pains. Unfortunately very few such operations have been carried out for the deliberate relief of headaches, but in cases done chiefly for vasospastic states in the arm, Love and Adson (1936) found that of 16 cases of concomitant headache the headaches were relieved in 12. The efficiency of this method in relieving pain, I find, has been questioned by White (1942) and Telford (personal communication). Whether or not relief is obtained by sympathectomy does not help in settling the route of conduction of the painful impulse, because relief when it is obtained by this operation can easily be explained by destruction of those pathways along which the original disturbance that initiates the painful impulse is conveyed. In other terms, sympathectomy destroys the motor and not the sensory arc of the mechanism of migraine.

My series of cases at least suggest that the painful impulse in migraine passes through the posterior trigeminal root, but they do not prove by any means that this is the main sensory pathway of the autonomic system of the head. Possibly the trigeminal pathway acts purely as a special defence mechanism. The main problem of the sensory pathways of the autonomic system still remains an enigma, and will possibly remain so until better methods of staining autonomic fibres have been discovered.

I have published these cases at this time because they throw light on the state of post-concussional headache, which is one of the main problems in His Majesty's Forces to-day. In many cases of post-concussional headaches no organic cause is demonstrable, either clinically or by encephalography, and many are labelled psychoneurotic or nervous. Possibly in many so-called nervous headaches the pain is not purely one of perception but is due to an unstable mechanism resulting from the injury, leading to atypical migrainous pains. This type of headache in Service cases is, I believe, much more common than the headache due to dural traction the result of adhesions.

THE SYNDROME OF HAEMORRHAGIC SUPRARENAL INFARCTION

BY

DORIS V. KEELE

AND

KENNETH D. KEELE, M.D., M.R.C.P.

Major, R.A.M.C.

The syndrome of primary infarction of the suprarenals is very rare, and unilateral infarction has not been described at all. There are only some 14 cases of haemorrhage into the suprarenals in adults recorded in the literature in which any description is made of the clinical picture. None of them were diagnosed in life, even at laparotomy, and all were fatal. The syndrome described in this paper is that produced by thrombosis of the suprarenal vein with resulting haemorrhagic infarction of the suprarenal gland, in an adult. Other causes of haemorrhage into the suprarenal are: (*a*) in the newborn; (*b*) in meningococcal and other acute infections, in which the picture clinically is that of the acute infection: the Friderichsen-Waterhouse syndrome is discussed in differential diagnosis here, and another case added to the 60 already described; (*c*) as a part of a general haemorrhagic state. The thesis put forward is that the suprarenal infarction syndrome is recognizable in life, and possibly treatable.

Case History

The patient (D. V. K.), an intelligent woman aged 32, was 8 months pregnant. The pregnancy had been normal except for occasional morning vomits, in some of which there had been streaks of blood. Two days previous to the illness the urine was albumin-free and the blood pressure 120/80. On March 28, 1941, at 12.30 p.m., she complained of feeling cold, after which she walked half a mile with no further complaint. Half an hour later pain appeared in the right side below the ribs—persistent, "like a stitch"—which made her put her right hand to the side and bend over to the right. This pain was exacerbated by the movement of the car and by walking. The pain below the right costal margin steadily increased in severity. There was no nausea, and the appetite was good. Pallor and sweating now became evident in spite of a strong pulse of 70 a minute.

2 p.m.—Patient restless in bed, in severe pain, which remained the whole time localized to a spot over the fundus of the uterus to the right of the umbilicus about 2 in. below the costal margin in front. There was no pain in the loin. Vomiting began at this time—copious, free, and sudden. This continued repeatedly until the end. Micturition was natural, and urine showed no haematuria. On examination there was some coldness of skin. Pulse 80, temperature 98°, respirations 20. Patient mentally quite clear. Abdominal tenderness was present at the site of the pain, which was located by her accurately with the finger-tips. There was no rigidity. Pressure on the tender region induced nausea and vomiting. The pain did not radiate or shift in any direction. It was very severe, and restlessness was marked, but it was described as "bearable."

5 p.m.—Admitted to the Radcliffe Infirmary and examined by Prof. Chassar Moir and Mr. D. C. Corry. The symptoms and signs remained the same. No abnormal signs were found elsewhere. White cells, 24,000.

10.30 p.m.—Laparotomy performed. A scarred adherent appendix was removed. Patient's condition was quite satisfactory until the skin sutures were being inserted, when mucus flowed into the trachea. This became blood-stained, and was followed by a profuse pulmonary haemorrhage, from which she died in spite of cardiac massage and tracheotomy. Caesarean section was performed, but the infant was dead.

Post-mortem Examination by Dr. Robb-Smith.—No abnormality was found apart from the lungs and the right suprarenal. Lungs showed diffuse haemorrhage filling the bronchioles in the substance of both. No evidence of active tuberculosis was found, though there was the scar of an old healed focus at the right apex. The heart was normal, the right ventricle empty. The right suprarenal was the size and colour of a large plum. The tissues surrounding this were very tense, so that when the organ was cut with a knife there was a sudden spurt of blood-stained fluid under pressure. The left suprarenal gland was normal. On examining the veins a thrombus was found extending along the suprarenal vein from its protrusion into the inferior vena cava. The thrombus in the large vein was older than that in the smaller branches by some 2 to 3 days. Blood culture was negative.

Summary of the Case.—The outstanding points are: (1) the gradual onset with "feeling cold"; (2) the ingravescent nature of the pain, growing in about two hours to great severity, and its accurate location; (3) the severity of vomiting, such that intestinal obstruction was seriously considered; (4) the absence of shock and of purpura; (5) exploratory laparotomy failing to make a diagnosis; (6) the death through pulmonary oedema progressing to profuse haemorrhage. Pathologically the case is unique in that there is none described with infarction of the suprarenal on the right side only, consequent on primary thrombosis of the suprarenal vein.

Diagnostic Criteria

The salient question is that of diagnosis. Is there a picture on which diagnosis of infarction of the suprarenal can be based? On retrospect it is my belief that in this case, and in some others collected from the literature, diagnosis is possible—that there is a clear-cut syndrome here which is not yet generally recognized. This rests mainly on: (1) the characteristics of the pain; (2) the severity of vomiting; (3) the surprising absence of "shock."

1. *Characteristics of the Pain.*—Both authors of this paper had been interested in the subject of pain over a period of some years. For this reason the description given by D. V. K. at the time of her illness was deliberately shaped to comply with Ryle's ten points (Ryle, 1936), which form the standard clinical description of pain. In the production of pain as a symptom, sensitivity is obviously a factor to be taken into consideration. For some years sensitivity to pressure pain has been used as a clinical guide to this factor, which it is believed is of definite significance (unpublished work). In the case of D. V. K. many tests had been made at various intervals of time, including four during the 8-months period of pregnancy designed to ascertain whether there was any detectable alteration in sensitivity during that period. Sensitivity to pain measured thus was near the average of 100 normal people in the case of D. V. K. For this reason, and because of her knowledge of the relevant features of pain, her evidence is of singular value from the diagnostic point of view. The pain in this case had the following characteristics:

Onset was gradual, not sudden, accompanied by a feeling of coldness. *Site:* From the first and during the whole 12 hours of the illness it was localized to a point to the right of the umbilicus about 2 in. below the costal margin. Location was accurate to an area about the size of a half-crown. There was no *shift* or *radiation*. *Severity:* At first mild in degree, it steadily increased until it was of great severity; but at its worst it was described as "bearable" by D. V. K. *Character:* First described as a "stitch"; later the word "cramp" was used. *Duration:* At all times it was persistent. And from its commencement until she was anaesthetized the pain never left her, except at the end of two hours for a brief period of about 2 minutes, when she surprisedly exclaimed that it had vanished. Then it returned with increased intensity. *Relief:* Nothing relieved completely. At first bending to the right appeared to be a more comfortable position. Veganin gr. 10 failed. Heroin gr. 1/12 gave some relief. *Aggravation:* Pain was made worse by any movement such as walking or the movement of the car. Pressure on the fundus of the uterus produced acute pain and nausea with vomiting. *Accompanying symptoms:* A feeling of cold preceded the pain. Vomiting occurred after about 3 hours, becoming persistent and repeated until operation. It had no marked effect on the pain. Micturition was free. There was no dysuria. The temperature remained between 98° and 99° F. throughout, the pulse about 80. *Tenderness* was located with the finger-tips to the area previously described, to the right of the umbilicus. There was hyperalgesia of the skin in this region. No rigidity was detected at any time. No pain or tenderness was present in the loin or in the region of the posterior renal angle.

2. *Vomiting.*—This was a symptom which obscured diagnosis. Starting about 3 hours from the onset, it was copious without retching, almost projectile in character, and repeated; there appeared to be little nausea between, when fluids were well taken. And in spite of it dehydration was not marked. Its character and persistence suggested intestinal obstruction.

3. *Absence of "Shock."*—This is so surprising as to merit a prominent part in the clinical picture: it is a finding so completely opposed to expectations in a patient with suprarenal disease, and with vomiting of the severity mentioned. Blood pressure was unfortunately not recorded during the few available hours, but three observers remarked on the full normality of the pulse at the wrist. Two days previously blood pressure was 120/80, and there was little detectable difference on palpating the pulse then and during the illness. The pulse rate never exceeded 88 in the half-hourly records taken over the last 6 hours. A white cell count showed a leucocytosis of 24,000.

The Clinical Picture in Other Recorded Cases

The above clinical picture is confirmed when analysis is made of the few available clinical records of similar cases, though it will be seen from the Table that many points are unfortunately omitted in these descriptions. Only one case, Arnaud's (1900), has been found which is comparable (Case 2)—that of a girl of 17 who developed symptoms 11 days after a severe burn. Here the pain is described as "epigastric." One feels that the word covers a wide area of abdominal wall which might well include the site described in the present case. Apart from this possible discrepancy there is similarity in the picture, so far as it is described, in the severity of the pain, the vomiting, and the duration of some hours.

In Case 3, described in detail by Pearl and Brunn (1928), there was haemorrhage into the right suprarenal, followed 7 days later by haemorrhage into the left. For its first phase this case, therefore, is similar: there was sudden onset of severe pain, which was first in "the right kidney region" and on the second day "under the ribs," with tenderness "in the region of gall-bladder." The advent of the left-sided haemorrhage was indicated by pain in "the left flank and under the ribs." Other points of similarity about this case are the absence of abdominal rigidity and of shock. Even on the 12th day of the illness the blood pressure was 120/80, and both suprarenals had by then been affected. Temperature, pulse, and respirations were all normal during the first day. In Cases 4 to 10 both suprarenals were involved. It is obvious that in these cases the combined areas of pain each side of the umbilicus might be described as "epigastric." Actually it will be seen that 3 are so described—one as "diffuse," one as in the "left kidney region," and one as under the costal margin, left first and then right. The last—Case 10—had no pain, but was tender under the costal margin.

Now to summarize regarding the characteristics of the pain. The localization was definite and in an unusual site in the present case. From the 10 cases quoted, in 4 this same site is described and identifiable; in 5 others the word "epigastric" or "diffuse" is used. These words at least localize the pain to the front of the abdomen rather than the flanks, and inaccuracy of observation may well account for lack of more precise siting. In one the pain is described as in "the kidney region" only. It is my opinion that this area of suprarenal pain is definite and probably of as much diagnostic value as pain and tenderness over MacBurney's point in the right iliac fossa. Observation of further cases will of course settle the issue. Pain in the loin is not as constant as in the anterior site.

The absence of rigidity is almost a constant finding in all the cases even after some days' duration, at a time when other abdominal catastrophes are almost certainly productive of this sign. Temperature, pulse, and respiration rate all remained normal in the majority of those cases in which they are recorded. In Pearl and Brunn's (1928) case fever is recorded on the 7th day. In Hall and Hemken's (1936) case fever of 104° F. was present terminally. The pulse rate remained below 100 in 5 out of 7 cases. In the one case (No. 8) where it was 120 there was accompanying pancreatitis.

Add 2 cases found in coma—both adrenals involved—and 2 cases in lunatics. C.M.—Costal margin.

Respirations in the present case were not raised until operation, when the patient showed distress under the anaesthetic. In the only other cases in which the rate is quoted it was 50, 32, and 45 per minute. These high rates suggest the presence of pulmonary congestion, though limited to a stage not revealed, as in the present instance, by profuse pulmonary haemorrhage. Basal rales were found in 2 cases. Vomiting of severe degree formed a prominent feature of the syndrome in 8 of the cases. It is mentioned as severe in 3 cases, and in only 2 is it omitted. Blood pressure is recorded in only 2 instances. Such readings as 120/80 and 145/95 correspond with the absence of the signs of shock found in most cases. In the present case it is probable that there was little change from the pressure of 120/80 taken before the illness. The mental state of all patients was clear, except in Case 2 after a week's illness. This contrasts with 4 other cases quoted—two by Arnaud and Laignel-Lavastine in which the patients were found in coma, and two occurring in lunatics (Munson, 1907; Severn, 1923)—a melancholic and an idiot. The white cell count has been found raised in all 4 cases in which it has been recorded. Figures of 24,000, 16,000, 20,000, and 52,000 raise the question of infection, but are equally well accounted for by infarction. Haemorrhage, either purpuric or from other organs, has been absent in all cases, except in the present one, in which it was terminal from the lungs. There was no evidence of any haemorrhagic diathesis in the case of D. V. K. Tonsillectomy had been performed 8 years previously, being followed by a miscarriage without abnormal haemorrhage. The absence of purpura in all cases is a point of interest, bearing in mind its constancy as a part of the Friderichsen-Waterhouse syndrome.

The duration of the illness has been variable. In 4 of the 10 cases death has occurred in less than 24 hours. In the others the illness has lasted from 36 hours to a period of months. This indicates that there must be all degrees of infarction. In fact, it is known that sometimes blood cysts are formed. Arnaud quotes a case in which a cyst weighing 4 lb. was found post mortem. The suprarenal tissue was entirely destroyed. The patient had had attacks of pain for a period of years, presumably due to repeated haemorrhages.

Differential Diagnosis

The main diagnostic problem is anatomical. In the case of infarction into the right suprarenal, diseases of the pleura, the gall-bladder, kidney, appendix, and alimentary tract are possible sources of diagnostic difficulty. In the case here described the uterus was enlarged by 8 months' pregnancy, and the provisional diagnosis made before laparotomy was that of a twisted ovarian cyst, or degenerating or twisted fibroid. A comparison of the picture described in the case history shows on retrospect the differences between most of these conditions and suprarenal infarction. These differences lie in the characteristics of the pain, which is not like a colic, and the site of which does not correspond to gall-bladder or renal pain, and is too high for the pain of appendicitis. The strict localization and the absence of radiation are both positive evidence of the suprarenal origin of the pain. The vomiting suggests intestinal obstruction, and such a diagnosis may be disproved only by laparotomy.

Exploratory laparotomy was performed in 4 cases. In none was the diagnosis made at this time. This raises, in my opinion, the most important feature of all. In an exploratory laparotomy, if the usual sites of acute abdominal conditions are found to be normal then the suprarenals should be examined. In most cases palpation alone will suffice, since when there has been haemorrhage the gland is the size and consistency of a large plum. If doubt still remains it would be possible to inspect the region. Retroperitoneal haemorrhage will be visible as well as the plum colour of the infarcted gland itself.

Arnaud, in his classification of the picture of suprarenal haemorrhage in adults, describes three clinical types: (1) Peritoneal type, into which fall the cases here discussed with abdominal pain and vomiting. (2) Asthenic type, characterized by asthenia alone, leading to death: the exitus of the two psychotic cases suggests this type. (3) Nervous type, in which the patient is found in coma or delirium, and is seen post mortem to have no cerebral lesion, but bilateral suprarenal haemorrhages: into this group fall the two cases of Arnaud and Laignel-Lavastine mentioned above. Differential diagnosis in Groups 2 and 3 must be considered impossible. Lavenson (1908) and Keith Simpson (1937) add the type in which sudden death occurs with no ascertainable cause and in which bilateral suprarenal haemorrhages are found post mortem. All these types occur in adults. In none of the cases quoted is there evidence of infection being the causative factor.

Causes of suprarenal haemorrhage may be classified as follows: In children two main types occur:

1. *Haemorrhage into the Suprarenals in the Newborn.*—Birth trauma is undoubtedly the cause here. Of 8 cases described by Levinson (1935) 6 were breech deliveries and 2 Caesarean sections: the latter two infants had been slapped on the loins to revive them. Owing to the involution of foetal cortex about the time of birth and its replacement by vascular tissue in a

loose stroma, haemorrhage is facilitated at that stage by trauma. Even in this type, however, operation proved successful in the case of Corcoran and Strauss (1924), in which laparotomy was done for a mass palpated in the left loin and left iliac fossa, and a bleeding-point ligated. This case establishes the fact that operation is feasible in cases of haemorrhage into the suprarenal. It is probable that small haemorrhages occur which heal and finally end in calcification of the suprarenal or in fibrotic change.

2. *Friderichsen-Waterhouse Syndrome.* — This syndrome occurs in older children. It is typified by the following case, the first of its kind to be seen by me.

> L. R., aged 5 months, was noticed by the mother to be restless and feverish in the night. In the morning a blotchy rash was observed on the forehead; no vomiting; drowsiness was present during the last hour. Examination showed extreme cyanosis, large purpuric patches all over the body; pupils unequal and fixed; tachycardia about 150; vomiting. Within an hour the child went into coma and died. Necropsy showed bilateral haemorrhage into both suprarenals. The brain and other organs were normal, except that there was congestion of both lungs. Blood culture was not done and the veins were not examined for thrombosis.

This clinical picture is in contrast to the syndrome in the adult due to infarction where there is no purpura, cyanosis, or delirium. The Friderichsen-Waterhouse syndrome occurs also in adults, and recently I have seen a typical case in a man aged 23, who came into hospital with purpuric patches, confluent on the feet and some 2 in. in diameter on legs and arms. This patient became comatose while being examined, at which time his blood pressure was only 70 mm. Hg systolic. Blood culture showed meningococci. He recovered on sulphapyridine therapy. This picture cannot be confused with the cases of primary infarction of the suprarenal gland. The purpura is in these cases the result of injury to capillary walls by the meningococci, which can be cultured from the purpuric patches. The two comatose cases described by Arnaud and Laignel-Lavastine might well fall into this fulminating meningococcal group.

Thrombosis of the suprarenal veins may occur in such patients and give rise to abdominal symptoms, which, however, will be obscured by the patients' mental state. Other organisms besides the meningococcus may produce suprarenal haemorrhage with purpura—but very rarely.

3. *Thrombosis of the Suprarenal Vein.*—This, according to Hall and Hemken, is the commonest cause of suprarenal haemorrhage in adults. It presents the syndrome of suprarenal infarction here described.

4. *Any Generalized "Haemorrhagic" Condition.*—This may show haemorrhage into the suprarenals. Such is the case, described by Lewis (1921), in an infant of 3 weeks which died of convulsions 5 hours after an operation for hare-lip. At necropsy, haemorrhage was found into pancreas, lungs, suprarenals, and other organs.

From this description of the types of suprarenal haemorrhage it will be seen that each presents a fairly distinctive clinical picture. These four groups summarize the clinical pictures in cases of fatal suprarenal haemorrhage. It has been shown by Snelling and Erb (1935) that in the newborn death does not always ensue on haemorrhage. Suprarenal glands examined later in life have shown calcification and haemosiderin deposition—i.e., evidence of previous haemorrhage. This calcification may be visible radiologically.

No similar case has been reported in adults, but now that cases of fulminating meningococcal septicaemia can be saved, as in the case described above, such haemorrhages may be expected, possibly with subsequent calcification visible radiologically. It should not be assumed that all cases of calcified suprarenal glands result from tuberculosis. The suggestion is tentatively put forward here that some cases of Addison's disease with "atrophic" or even calcified suprarenals are the result of old haemorrhage into the gland. No such case, so far as is known, has been recorded, but in a case of Addison's disease treated by grafting foetal suprarenal glands into the rectus sheath (Bailey and Keele, 1936) there was dramatic and successful response of blood pressure and symptoms, though not of pigmentation. This patient was last seen 6 years later, quite well. Relevant to the present thesis is that 6 months before her symptoms developed she had had cholecystectomy for abdominal pain. The gall-bladder appeared normal and the patient's symptoms were not improved. Were the symptoms produced by disease of the suprarenals?

Pathology

Post-mortem findings have been limited to changes in the suprarenals in most cases. Carcinoma of the bronchus was an associated finding in Case 4 (Altschule, 1939). Pancreatitis obscured the clinical picture in Case 8 (Lavenson's). "Chronic nephritis" was found in 2—those of Michaux and Marsset and of Lavenson. This association has probably more than coincidental significance, as it has been noticed by French workers (Michaux and Marsset, 1923), and recently such a case has been found by Dr. Robb-Smith (personal communication). Pulmonary haemorrhage was observed only in the present case though congestion was mentioned in Case 8.

Unilateral infarction of the suprarenal has been found only in the present case and one other (Arnaud), in both instances on the right side. In Case 3 the right side was involved first. In Cases 7 and 9, however, the history suggests that the left side was involved before the right. In all cases the suprarenal glands have been replaced by blood, often clotted, contained inside a capsular layer, or (in 5 cases) infiltrating into the retroperitoneal tissues to a varying extent. This infiltration may be extensive and produce a palpable tumour in the flank. Such a case in an infant was operated on and cured (Corcoran and Strauss, 1924).

Histologically the medulla of the gland is completely replaced by blood. In most instances a layer of cortex remains. Thrombosis of the suprarenal vein is an important and frequent finding. In 6 of the 10 cases it is specifically described, and is not mentioned in the others. That this thrombosis of the vein is not a sudden event is shown by the fact that in the present case the thrombus in the main suprarenal vein projected into the inferior vena cava, and was estimated to be from 2 to 3 days old, whereas that in the small venous radicles was more recent. Thrombus had spread, therefore, from large vein to small, and infarction of the gland was so produced.

The cause of death in the present case was the diffuse bilateral pulmonary haemorrhage; in the other cases it presumably was acute suprarenal insufficiency. In the post-mortem findings of cases of Friderichsen-Waterhouse syndrome pulmonary congestion is commonly mentioned, and in view of the present case it would seem that suprarenal insufficiency does produce some change in pulmonary circulation.

Pathological Physiology in Suprarenal Infarction

Symptom production in suprarenal infarction and biochemical changes that ensue are shrouded in mystery and complexity. The pain in the right side is of the "referred" type. Its accurate location corresponds with thoracic segment 10. It results either from afferent stimuli passing up from the medulla of the gland itself or from retroperitoneal irritation. The state of tension of the gland from which blood spurted post mortem and the mild degree of retroperitoneal infiltration would favour the first hypothesis in the present case. The medulla of the suprarenal receives a large number of sympathetic fibres that come from the coeliac ganglion and plexus, which incorporates the two splanchnic nerves on each side. Fibres to the suprarenal are plentiful and mostly preganglionic, and medullated. From the site of pain in the present case it seems justifiable to suggest that the segment from which the outflow occurs is Th. 10.

The vomiting is remarkable, and no easy explanation is available. One can only compare it with the crisis in Addison's disease, the mechanism of which is imperfectly understood. Pulmonary haemorrhage is even more difficult to account for, though it is obviously related in some way to the acute suprarenal insufficiency. To try to say how related would be merely to indulge in guesswork. It does appear, however, that there is no reason why this patient should have died if pulmonary haemorrhage had not occurred, since the other suprarenal was intact. But possibly it, too, would have become infarcted, as happened in Pearl and Brunn's case.

Biochemically there is no evidence at all as to what changes are taking place in such acute suprarenal disease. In adrenalectomized dogs detectable changes in blood chemistry do not occur until the second day at the earliest. This applies to values of blood cholesterol, sugar, urea, sodium, potassium, and chloride; nor does blood pressure fall or pulse rate rise until the second or third day. These findings are curiously confirmed by the clinical normality of blood pressure and pulse in these cases of suprarenal infarction described.

The vascular supply of the suprarenal gland is remarkable. Three arteries converge to produce the most vascular organ per gramme in the body. The vein arises from sinusoids in the medulla. Its walls contain a considerable quantity of muscle, and the blood in it is oxygenated, being "arterial" rather than "venous." Occlusion of this large vein results in a haemorrhagic infarction of the gland, which starts in the loose medullary tissue, destroying it completely. The cortex is also destroyed, but often a thin rind of it escapes, helping to form a capsule round the haemorrhagic area. Later this may rupture, the blood spreading down into the perirenal fat and into the retroperitoneal tissues.

The cause of primary venous thrombosis is unknown, though it occurs as a rarity, the portal vein being the commonest of the visceral veins to be affected.

Pregnancy as a Factor.—One other case occurring in pregnancy has been found—in a girl aged 18 with hyperemesis gravidarum. No other clinical facts are given; but at necropsy it was seen that haemorrhage was into the left suprarenal more than the right. Thrombosis of the suprarenal vein was marked.

Summary

A case of haemorrhagic infarction of the right suprarenal gland is described. The clinical picture is compared with that of cases in the literature, and it is considered that this rare condition may be diagnosed in life. The characteristics of the pain—particularly its site, the repeated vomiting, and the remarkable absence of shock—present a well-defined but hitherto unrecognized syndrome.

Differential diagnosis is discussed, with particular attention to other clinical types of suprarenal haemorrhage: (1) haemorrhage in the newborn; (2) Friderichsen-Waterhouse syndrome; (3) haemorrhagic disease. Examples of these are described.

The failure of laparotomy to diagnose cases is noted and a plea put in for exploration of the suprarenals at operation if no other adequate pathological change is found; ligation of a bleeding-point or excision of the gland are measures which might be adopted.

I would like to put on record my deepest gratitude to Prof. Chassar Moir for his great skill and for his kindness to my wife in her illness and to me afterwards. He made available to me all his case notes, and his help has been invaluable. Dr. A. H. T. Robb-Smith has also been most generous in permitting me to have full details of the pathological findings, and in discussing them with me.—K. D. K.

F. E. Maisel and E. Somkin (*J. Allergy*, 1942, **13**, 397) have published a preliminary report on the treatment of the asthmatic paroxysm with nicotinic acid. They found that (*a*) severe asthmatic attacks were controlled within 3 to 5 minutes, and improvement lasted 3 to 15 hours, in 16 of 21 patients by the intravenous injection of 0.1 g. of nicotinic acid; (*b*) 5 of 9 chronic asthmatic patients were benefited by 0.2-g. doses given orally three times a day before meals and on retiring; and (*c*) 11 of 18 patients receiving intravenous therapy followed by oral therapy showed decided improvement in their asthma. The patients experience a flush and a sensation of heat, then often begin to cough, and expel tenacious mucous plugs. The beneficial effect is thought to be produced by the strong vasodilator properties of nicotinic acid, relieving the bronchospasm or directly affecting the pulmonary vessels, and has no bearing on vitamin deficiency. The patients were mostly beyond middle life, often with a well-marked infective element and not responsive to ordinary allergic methods of therapy. No patient developed any disturbing symptom.

THE HERRING AS A SOURCE OF VITAMINS A AND D

A COLLABORATIVE INVESTIGATION

Conditions determining Food Value

The importance of a food as a source of any particular nutrient depends primarily on two factors—the amount of the nutrient present and the quantity of the food eaten. Most recent books on dietetics and nutrition include the herring among the "protective foodstuffs," and justify this by referring to its excellence as a source of fat-soluble vitamins (cf. Plimmer and Plimmer, 1938; Bourne, 1941; McDonald, 1938; Mottram, 1938, 1940; McCarrison, 1941). Only Wokes (1941) appears to have had doubts.

Examination of the evidence for this belief is rather disconcerting. In the tables of Fixsen and Roscoe (1937-8, 1938-9) four references are given, and they derive from only three authors, one of whom was reviewing the physiology of the sterols and gave no experimental data of his own. More recent papers have been exceedingly scanty, both in number and in informativeness, though an exception on the latter score may be made for that by Lunde *et al.* (1937), who give values for the body oil of herring as under.

Condition of Herring	Vitamin (I U. per 100 g. Oil)	
	A	D
Fresh, winter	200 to 2,800	9,000 to 15,000
Kippered	Unaffected	11,500 to 14,500
Canned and stored	Decreased	7,000 to 14,000
Canned, kippered	Trace	

These authors do not clearly differentiate between canned herrings that have been submitted to preliminary kippering and those that have not, but they remark that "since kippered herring contains about 12 to 13% of oil, the canned product is a food with . . . a high vitamin D potency." This seems to us to be a conclusion of little practical bearing unless consumption data are also taken into account, so enabling us to assess the importance of the herring as a source of vitamins A and D in the national diet.

From certain figures published by the Herring Industry Board for the year 1937, and made available to us by the kindness of Dr. Magnus Pyke of the Ministry of Food, an idea is to be had of the *per capita* consumption of herrings in this country. It amounted to approximately 1¼ oz. a week, of which just under 0.6 oz. was fresh herring. One of us (J. A. L.) has been able independently to obtain a check on these figures, with very satisfactory agreement. The figures for the vitamin D content of herring-flesh oil have little nutritional significance without an accompanying statement as to the oil content of the flesh, which is known to vary considerably. Our own findings, given below, confirm this and cover a range from 3.6 to 20.2% in fresh herring.

The contribution to their average intake of vitamins A and D obtained by the population from herrings clearly cannot be satisfactorily calculated on the basis of published data. We therefore decided to reinvestigate the matter, examining both canned and fresh herrings.

Methods of Testing

Vitamin A was determined by the spectrophotometric technique on the unsaponifiable matter separated from the glycerides of the oil; vitamin D was estimated by one or other of the recognized methods of biological assay. The determinations of vitamin A were all carried out in laboratory L. The biological assays for vitamin D were carried out in three different laboratories, though not on any one sample at all of them. In two the line test was used, in the third a radiographic technique; one assay in laboratory R was done by the chemical method of bone analysis. The details of technique and experimental design resembled those recommended in the *British Pharmacopoeia, 1932,* and minor modifications and differences are quite unlikely to have introduced differences in result falling outside the usual range of experimental error encountered in such tests.

Vitamin D Tests

Two main series of samples and certain special oils were examined. The first series consisted of oils expressed from five different brands of canned herrings, some with and others without tomatoes. All were examined in laboratory C, and two in laboratory G (one of them in two independent assays). Exploratory tests had been carried out at levels based on the vitamin D values reported in the literature for herring body oil, and all produced in the test animals healing quite insufficient for assay purposes. Tests were then made at higher dose levels, the oils being separated in laboratory C by pressing the fish in muslin and removing water by centrifuging. (The exploratory samples had been separated by ether extraction of the tissue, after grinding it with sodium sulphate.) The results obtained with these samples are given in Table I. The discrepancy between the values found by laboratories C and G for oil 4 has not been resolved: of the two assays carried out on that sample in laboratory G, the second (the lower) is the more accurate, the limits of error, for P=0.05, being 84% to 119%. The error was calculated from a variance analysis: this assay, which was conducted on 40 animals, exclusive of negative controls, is probably the most accurate of those made on the first series of samples 1 to 5.

TABLE I.—*Vitamin D in Canned Herring*

Sample	Brand	Tomato	Oil in Flesh (%)	Vitamin D (I.U.)		Laboratory
				Per 100 g. Oil	Per oz * Flesh	
1	A	+	23 0	750	48	C
2	B	+	10 0	550	15	C
3	C	+	16 5	1,720	80	C
				1,980	92	G
4	C	—	18 8	730	35	C
				2,300 : 1,940	120 · 106	G
5	D	—	18 0	650	33	C

* By calculation from preceding two columns.

It is clear that the values found for the body oil of canned herrings are much below the figures reported in the literature for canned or fresh herrings. This raises the question whether the discrepancy is due to variation in the antirachitic value of the fresh fish, to losses during canning, or to the error of biological assay. In view of the relative consistency of these results, both in themselves and with those reported below, we consider that our values are reasonably correct for the samples examined by us. The results with fresh herrings, given later in this paper, do indeed point to a real difference between the vitamin D contents of canned and fresh herrings, for which we are not able to offer an explanation.

In order to establish that the method of extracting the oil with ether does not give rise to any misleading results, a batch of August herrings containing 15.5% of oil was divided, one fillet from each fish being used for solvent (diethyl ether; S.G. 0.735) extraction of the oil and one for pressure extraction. The resultant oils (samples 6 and 7), which were so prepared in laboratory T, were examined in laboratories R and G. In laboratory R they were compared with the international standard preparation in the usual way, and gave values of 1,800 I.U. per 100 g. (expressed oil, sample 6) and 2,000 I.U. per 100 g. (extracted oil, sample 7). The errors of the logarithms of the potency ratios of oil and standard in the two tests were ±0.00726 and ±0.00758; the difference is perhaps suggestive, but it was found not to be significant (t=0.37, P=0.7). A more elaborate comparison was made in laboratory G, where each oil was fed at 3 doses to 16 animals, so distributed that 96 animals were used in six strictly comparable litter-mate groups. It was found that the relative activities of the two oils were as 1.66 : 1 in favour, curiously enough, of the extracted oil. This confirms the result suggested by the finding in laboratory R; for in this more extensive comparison the error was estimated by means of a full variance analysis, and calculation showed that the difference just has statistical significance (t=2.0, P=sl. > 0.05). The reason for the higher activity of the extracted oil is unknown, although one of us (J. A. L.) has encountered a similar phenomenon with the vitamin A of liver oils. A possibility is partial denaturation of the protein by the alcohol in the ether used for extraction, with a resultant liberation of vitamin D held in some kind of combination with protein. However this may be, the results dispose of any fear that ether extraction, as carried out, had appreciably reduced the vitamin content of the oils tested.

Next, two samples of herring oil were extracted in laboratory T from fresh fish, the method used being identical with that employed in preparing sample 7. The results of the tests on these two samples—8 and 9—are included with others in Table II. The discrepancy between the two assays of sample 8 is rather large, but evaluation of its significance has not been possible. The assay in laboratory G had limits of error, for P=0.95, of 84.5% to 118%. In spite, however, of the discrepancy noted, the amounts of vitamin D in these fresh herrings are clearly considerably greater than those found in the five samples of canned herring, or in the two samples (6 and 7) of fresh-herring oil, expressed and extracted, assayed in laboratory R.

TABLE II.—*Vitamin D in Fresh Herring*

n.e.p.=no evaluation possible.
* By calculation from preceding two columns.

The samples in the second main series were prepared in laboratory T from fresh herrings caught at different seasons. Again only the fillets were used (that is, the skin and small bones were retained, but head, tail, and backbone were rejected); they were, like the previous samples, minced, dried with anhydrous sodium sulphate, and rapidly extracted with ether. As will be seen from Table II, they represent fish in various stages; these are indicated in the table by numbers based on the classification of Lovern and Wood (1937). These samples were assayed in laboratory R; the second assay on sample 10 was conducted by the bone analysis (prophylactic) procedure. The figures for samples 6 to 9 are also included in the table for completeness and comparison. Incidentally, it should be noted that the probable limits of error for the assays carried out in laboratory R are likely to have been somewhat underestimated, as no account could be taken of the error of the slope of the dosage-response curve in each test: the calculated limits of error for all assays carried out in laboratory G take this into account. The results obtained in laboratory C were not suitable for the usual type of statistical analysis, and may be a little more inaccurate than those carried out in laboratories R and G.

In spite of certain inconsistencies encountered in these tests, a moderately clear picture is presented by the fresh-herring oils, which appear, as might be expected, to increase in vitamin D content as they decrease in amount (per unit weight of tissue). This tends to level out the vitamin D contents of the flesh, although these still show a range of 84 to 480 units per oz. The average of all eleven samples is 9,400 I.U. (range 1,900 to 26,000 I.U.) per 100 g. oil and 240 I.U. per oz. of flesh.

It is perhaps worth noting that whenever an assay was repeated in laboratory R on a sample of oil previously assayed there a lower value was obtained (samples 10, 12, and 13). The differences were statistically significant for oil 10 (three months' interval, P=0.02) and for oil 13 (1 month's interval, P=0.03), but not for oil 12 (1 month's interval). It is probably not justifiable to take these figures as in any way proof of the instability of vitamin D in ether-extracted herring body oil, held, like these samples, at 0° C., but they may perhaps suggest the need for care and speed in handling samples of such oils intended for vitamin assay.

Vitamin A Tests

The figures for vitamin A content are shown in Table III. They were obtained spectrophotometrically at wave-length 617 mμ, using the blue colour produced with antimony trichloride, and calculated from the formula

Table III.—*Vitamin A in Herring*

Sample	Description*	Oil in Flesh (%)	Vitamin A (I.U.)	
			Per 100 g. Oil	Per oz. Flesh†
3	Canned, with tomato	16·5	300†	15‡
4	Canned	18·8	530†	28‡

* For further details see Tables I and II.

† By calculation from other columns, except those marked ‡, which are results of direct determinations.

$$\text{I.U. per g.} = E^{1\%}_{1\ \text{cm.}}\ 617\ \text{m}\mu \times 510.$$

Two purely qualitative tests in laboratory G on the oils from samples 4 and 8 gave results for absorption in the ultra-violet at 325 mμ consistent with those obtained by the more precise assays at laboratory L. When the samples of canned herring with tomatoes were examined a phase separation of lycopene had to be included to prevent interference with the antimony trichloride reaction of the vitamin A: apart from this the test, like the others, was carried out on the unsaponifiable matter of the oil previously separated by means of sodium sulphate and ether from the flesh. There may be some significance in the fact that the values for canned herring all fall at the lower end of the range for fresh herring; but the number of results obtained is not, in our opinion, sufficient to justify any definite conclusion about the effect of canning on vitamin A in herring flesh.

Discussion and Conclusions

If the results obtained by us are genuinely representative of herring body oil, they tell a somewhat different story from what published figures might have suggested. A paper by Ranganathan (1941), though concerned mainly with Indian fish and shark-liver oils, gave a few figures for (presumably) body oils from sardine, mackerel, ray, and plough-fish: these range from 16,000 to 25,000 I.U. of vitamin D per 100 g.—round about the higher limit found by us for herring oil: no information is given about the oil contents of the fish or as to the presence or absence of liver and gut oil. A recent paper by Holmes *et al.* (1941) also gives some data for the body oils of eel, sardine, herring, menhaden, and rose-fish. Figures of 5,000 to 20,000 I.U. of vitamin D and 34,000 I.U. of vitamin A per 100 g. of oil are quoted, again without reference to the amount of oil in the whole fish. Further, Pugsley (1942) gives some figures for the Pacific species, *Clupea pallasii*, which is closely related to our own *Clupea harengus*. He found 7.3% of body oil in one sample of the fish, and the oil contained 3,300 I.U. of vitamin D per 100 g. (68 I.U. per oz. flesh), but no vitamin A. We ourselves are not, however, claiming to have made any exhaustive study of the factors affecting the fat-soluble vitamins in herring muscle, or to have encountered the whole normal range of values, so that the figures reported by other workers should be useful as a reminder that our conclusions apply only to herrings having vitamin contents that fall among the values found by us.

However, in calculating the contributions made by herrings to the daily human intake of vitamins, the figures given by these authors are of no very great assistance. In estimating the value of herring as sources of vitamins A and D, therefore, we have thought it best to rely on our own figures. Assuming that the average amounts of vitamins A and D per oz. of fresh herring are 40 and 250 I.U. respectively, that vitamins A and D are lower in the canned fish by the same proportion, so that the respective values per oz. are 8 and 50 I.U., and taking the average weekly consumption per head as 0.7 oz. of fresh herring and 1.2 oz. of canned, bloatered, or kippered herring—both slight overestimates; ignoring, furthermore, the high probability that smoking and curing involve greater losses of fat-soluble vitamins than does canning, we are able to estimate an outside value for the average individual daily intake of vitamins from these sources:

	Units per oz.		Units consumed per Day	
	Vitamin A	Vitamin D	Vitamin A	Vitamin D
Canned, etc.	8	50	2	10
Fresh	40	250	4	25
Total			6	35

It is of course admitted that some individuals with a relatively high consumption of herring may obtain from them a useful proportion of their requirements of vitamin D, but this will only be at the expense of others who are deriving no appreciable amount from the same source.

Considered as an item in the national dietary, apart from such individual exceptions, it would appear, therefore, that the undoubted value of this fish as food must be due rather to its content of protein and of adventitious calcium from unavoidable herring bones than to its vitamin contents—at any rate, when consumed on what appears to be the usual scale in this country. It may be pertinent to add that available recent information as to the amount of vitamins A and D in salmon, canned or fresh, seems to indicate that the same considerations apply (cf. Pyke and Wright, 1941).

Such conclusions seem to us to be relevant not only to the problem of designing diets adequate for normal or optimal nutrition but also to the concept of adequacy itself, in so far as this is to any extent based on a study of actual dietaries, for which the nutrient analyses must generally, perforce, be taken from averaged published figures.

Summary

The average amounts of vitamins A and D in fresh herring were of the order of 40 and 250 I.U. per oz., and in canned herring may be about 8 and 50 I.U. respectively. The average daily contribution made by herrings to individual human intakes of vitamins A and D in this country is insignificant—namely, about 6 and 35 I.U. respectively.

Some of the statistical data included in this paper were calculated by Dr. K. H. Coward, and Dr. J. O. Irwin assisted with advice on variance analysis. To both of these we are much indebted.

SICK ABSENCE AMONG MUNITION WORKERS

BY

A. MASSEY, C.B.E., M.D., D.P.H., D.P.A.
Medical Officer of Health

AND

R. C. M. PEARSON, M.D., M.R.C.P.Ed., D.P.H.
Deputy Medical Officer of Health
City of Coventry

The medical profession has a vital contribution to make at the present time in the battle of production. In the fourth year of war, factory workers may begin to feel the strain unless working hours and conditions continue to be determined on scientific lines to ensure compatibility with optimum output. In this and allied matters medical opinion is indispensable. Moreover, it is of course important to minimize loss of working time due to manifest sickness, and for this reason continued research into the medical aspects of absenteeism is necessary. In this connexion the figures relating to a recent inquiry we have made may be of interest.

TABLE I.—*Incidence of Sickness causing Absence from Work—Percentages of All Workers. (Figures relate to Seven Engineering Firms—Total Employees: M., 8,049; F., 3,397—during Period Nov., 1941, to April, 1942)*

The inquiry covered seven engineering firms the managements of which agreed to supply information covering the period Nov., 1941, to April, 1942, in regard to the causes and extent of loss of working time on account of sickness. Special forms were supplied for the purpose, and our thanks are due to the firms and to the industrial medical officers concerned for their helpful co-operation. The firms were of all sizes, and thus represent a fair cross-section. The information collected has been analysed and is briefly set out in the tables.

Comments on the Tables

The tables are more or less self-explanatory, but a few comments on them may be useful. The equivalent of 50% of all male employees lost some working time on account of sickness during the six months under review. The figure for females was 45%. In explaining the higher absentee figure for males, the age factor may have a bearing. The average age of male employees is probably greater because of the partial comb-out of younger men for the fighting Forces, whereas among females the young preponderate. It is conceivable that the increasing recruitment to industry of older, married women, made possible by the large-scale wartime nursery provision, may tend in future to increase somewhat the percentage of sickness absenteeism among females. The greater physical demands generally made of males by the nature of their work is also a relevant factor, although this is set off to some extent by the greater liability of females to nervous disabilities connected with the repetitive work allotted to them.

As usual the "colds and influenza" group is shown to be the greatest single time-loser, and in both males and females nearly a quarter of all absentees are sufferers under this heading. A notable exception is provided by the females in Firm 7 (Table I). This firm is liberal in its provision of prophylactics against colds, and it appears that the women and girls avail themselves more readily than the men. At four of the other firms, however, vitamin concentrates are also made available. But the figures concerning absence due to colds and influenza at these firms are not particularly favourable, although it is agreed by each firm that the incidence of colds is lower among the employees regularly taking vitamin concentrate than among those not so doing.

Males are in a majority under the heading of respiratory affections, and females show the greater incidence of nervous conditions. There is a notable paucity of strictly occupational diseases. Accidents account for 6% of all absences in males and 5% in females. Certainly there appears to be no evidence that women are generally more "accident-prone" than men. The high accident figures in Firm 4 (Table I) are probably explained by the inclusion under the heading of accidents of comparatively small injuries which elsewhere have been categorized as "other conditions." Although comparative pre-war figures are not available it is clear that there is an increase in factory accidents, due to wartime pressure of work, the larger proportion of inexperienced persons at work, and like considerations. According to the figures, little time is being lost by workers on account of dental conditions. It is

TABLE III.—*Percentages of Workers Absent Sick (All Causes) Month by Month (All Firms)*

	Nov.	Dec.	Jan.	Feb.	March	April
Males	8·2	7·1	9 1	8 5	8 5	8·7
Females	7·5	6 4	8·0	6·8	7·5	8·6

TABLE IV.—*Average Numbers of Working Hours Lost per Absentee (All Firms) in Respect of Each Disability Group*

	Nature of Disability causing Absence. (See Key in Table I)															
	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16
Males ..	65 8	106 9	82·1	148·8	102·5	100 4	113·2	10 0	100·0	65·6	75·6	142·3	95·0	126·4	—	98·0
Females ..	66·3	112·0	69·1	106·8	110 2	82 0	240·0	250·0	72·8	77·5	78·5	131·3	75·0	83 3	193·2	104·2

kely that in many cases lengthy dental work is being neglected nder the pressure of essential war work. It will be noted at "other conditions" constitute a considerable proportion f the causes of absence. This is due in part to the vague ature of some of the medical certificates received at the actories in respect of absentees.

Conclusion

In connexion with the health of factory workers, home ircumstances play at least as big a part as working conditions, nd it is ordinary sickness that is the chief time-loser. The roblem thus overflows from the field of industrial medicine nto the spheres of public health and general practice. The nquiry here reported brings out the need for improved and tandardized sickness records relating to factories, and underines the importance of explicit certification by medical ractitioners. In preventive medicine, all possible measures gainst the winter incidence of colds and influenza in the actories are a first requisite. A consideration of factory vorking hours is inseparable from the problem of sick absence. he health of munition workers, as of the general population, s on the whole being well maintained.

SUDDEN DEATH IN UNSUSPECTED RHEUMATIC CARDITIS

BY

J. T. QUINLAN, M.B., B.Ch., D.C.P.

(From the Department of Pathology, Torbay Hospital, Torquay)

udden death in unsuspected rheumatic carditis is a rare vent, and very few cases have been reported (Géraudel *t al.*, 1928 ; Thatcher, 1929 ; Breitenecker, 1931 ; Laplace, 939 ; Lisa, 1939 ; McNamara, 1941). The following is he record of a case occurring in an apparently healthy nfant.

Case History

An only child aged 2 years 8 months was apparently in xcellent health, playing with his toys, when he suddenly cried ut in distress and ran a short distance to his mother in an djoining room. He continued to cry loudly for a few minutes, nd then became faint. Death occurred within half an hour.

Necropsy.—The gross pathological findings were confined to he heart and right lung. Two infarcts were seen in the lung—ne near the apex, and the other, slightly smaller, on the lateral urface of the lower lobe. The base of the larger infarct neasured 1½ in. in diameter, and the cut surface in each case howed a characteristic triangular outline and a sharp demarcaion from the surrounding lung, in which there was no evidence f consolidation. Unfortunately, a careful dissection, with lemonstration of the emboli, was not attempted. Examination f the heart showed a general enlargement to 120 g. (normal 5 to 75 g.), as well as rheumatic mitral and tricuspid alvulitis. The vegetations on the mitral cusps were characterisically bead-like, firm, and pale, in contrast to those on the tricuspid, which were soft and pink, and evidently of a more recent origin. There was no evidence of pericarditis, and the cut surface of the myocardium did not appear unusual.

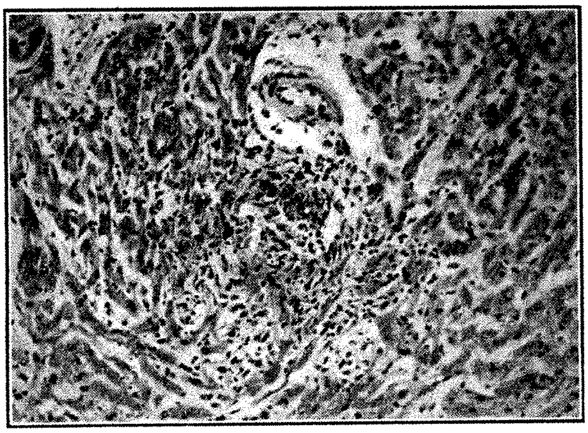

FIG. 1.—Typical Aschoff body in myocardium.

Histology.—The histological changes were focal in distribution, and several areas of myocardium showed no recognizable variation from normal. A few characteristic Aschoff bodies (Aschoff, 1904) were seen in the interstitial tissue (Fig. 1), and in some sections there was a diffuse infiltration by lymphocytes and polymorphonuclears between the muscle fibres. Some fibres in these areas were swollen and fragmented, with large irregular hyperchromatic nuclei, giving the impression of a rather acute degenerative process (Fig. 2). Bacteria were not seen in any of the sections examined.

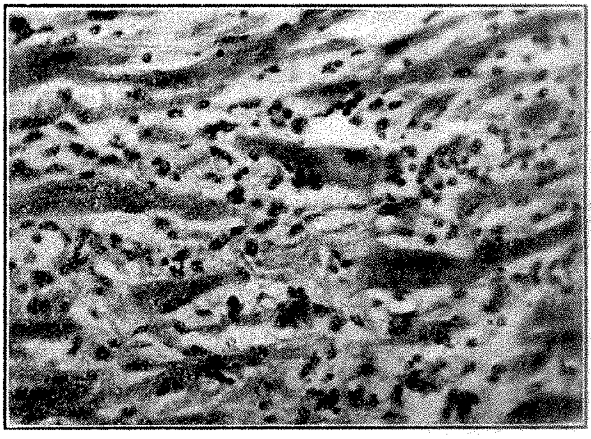

FIG. 2.—Myocardial fibres disintegrating.

Commentary

Severe fulminating carditis is becoming very rare in children (Miller, 1937), although subclinical rheumatism is common. The heart itself, when acutely invaded by the rheumatic process, only rarely gives rise to symptoms (White, 1937), and in this case it is probable that the urgent symptoms preceding death were due to the pulmonary infarctions.

The aetiology of lung infarction in general has been exhaustively studied (Belt, 1939), and embolic manifestations in rheumatic heart disease have also been investigated (Weiss and Davis, 1933). In a group of 174 cases of rheumatic heart disease infarction of one or more organs occurred in 45%, the lung being the organ most often affected, and in 21% of the series embolism played a chief or contributory part in the death of the patient.

An interesting feature of this case is the possible relation between the only previous illness and the fatal termination. The appearance of the heart at necropsy, as well as the histological findings, indicates that the disease had existed for some time before death, and it is possible that the attack of bronchitis from which the child had suffered six months previously may have been the initial manifestation of invasion by the rheumatic process.

The relation between upper respiratory infection and rheumatic fever has been studied by several workers (Wilson, 1940), and it appears that in some cases a severe cold or bronchial catarrh may usher in or precede by a variable interval the development of clinical rheumatism. The opinion of most workers in this field, however, is that respiratory infections are not a specific provocative agent in the occurrence of rheumatic fever (Hench, 1938).

In the histological examination the finding of characteristic Aschoff bodies was accepted as proof of the rheumatic nature of the infection, and the other components of the microscopical picture provided additional evidence in support of this conclusion.

Medical Memoranda

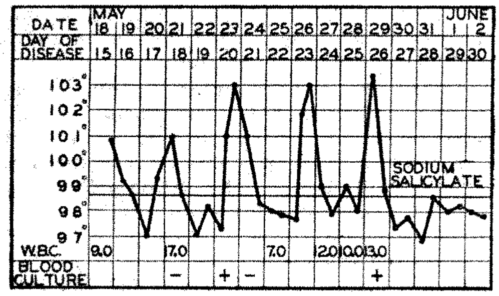
Meningococcal Septicaemia with a Malarial Type of Fever

A case with a regular and intermittent type of fever suggestive of malaria, but which proved to be meningococcal in origin, has recently been observed by me. The case resembles one reported in the *Journal* (Aug. 1, 1942, p. 129) by Dr. R. Priest.

Case Report

A 23-year-old soldier was admitted to hospital on May 18, 1942, complaining of soreness in the back. Two weeks previously he had had a fairly sudden onset of chilly sensations, followed by the appearance of tender red lumps, 1 to 2 cm. in diameter, on his shins, thighs, and elbow regions. A few days later symmetrical swellings developed below both knee-caps, and both knee-joints were painful. These lesions gradually subsided in a week. Three days before admission he developed a dull low-back pain.

On admission the patient's oral temperature was 101° F., and he appeared ill. The positive physical findings consisted of a few faint brownish non-tender blotches over both thighs and shins, point tenderness over the second lumbar vertebra, and enlarged tender inguinal lymph nodes. Urine and prostatic smears were essentially negative. The haemoglobin was 14.85 g. per 100 c.cm., and the total leucocyte count 9,000 per c.mm., with 75% polymorphonuclears. Over the first 12 hospital days there was a fairly abrupt temperature rise every two or three days, the peaks varying between 101° and 103° F. and falling rapidly. The elevations were accompanied by pulse rates of 70 to 80. A smear for malarial parasites was negative. Blood cultures, taken on four occasions, were twice positive for *N. meningitidis*, Group 2. The positive cultures were obtained just before the peak of a temperature elevation, the negative cultures at a time when the temperature was falling. Leucocyte counts made during pyrexial periods ranged from 12,000 to 17,000 and in the afebrile periods from 7,000 to 10,000 per c.mm.



The respirations remained normal, except that a rise occurred during one febrile episode. Sedimentation rates, taken over the first 17 hospital days, were nearly constant at 34 to 36 mm./hr. (Wintrobe). Nasopharyngeal cultures were negative for *N. meningitidis*.

Two tender red lumps developed on the inner aspect of the patient's right arm on the 7th day in hospital. These persisted 4 days. He complained of considerable stiffness in the knees and hips. Positive blood cultures were taken on May 23 and 29; but the first blood took 7 days and the second 4 days of incubation before *N. meningitidis*, Group 2, was definitely isolated. While awaiting a laboratory report on these cultures rheumatic fever was considered. The patient was given 4 to 5 g. of sodium salicylate daily for 5 days, beginning on the 13th hospital day. He thereafter was symptom-free and his temperature remained normal. Cultures of blood and sternal bone marrow taken on the 22nd hospital day were negative. However, beginning on the 23rd hospital day, the patient was given a total of 48.5 g. of sulphadiazine over a week's period, to lessen the chance of any relapse. Nuchal rigidity and splenomegaly were absent throughout the course of the disease.

Although meningococcaemia was early suspected in this case, repeated blood cultures and a prolonged incubation of them were required to establish the diagnosis. Before the aetiology of the disease was definite, malaria was considered owing to the regularity of the pyrexia, and rheumatic fever in view of the joint manifestations. Gonococci were sought for in association with the arthritic symptoms.

This case illustrates the bizarre picture which may be presented in meningococcal septicaemia. The malarial type of periodicity, together with the erythema nodosum lesions, makes it likely that both the present case and that reported by Priest had the same diagnosis, although no positive blood cultures were obtained in the latter.

PARASITOLOGY

Textbook of Clinical Parasitology: Including Laboratory Identification and Technic. By David L. Belding, M.D. (45s.) New York and London: D. Appleton-Century Company. 1942.

This book will make an instant appeal to all those who ar interested in medical zoology—protozoology, helminthology and entomology—whether from the point of view of th student of parasitology, the pathologist working in a laborator where clinical material comes for examination, or the clinicia who is occupied with the diagnosis and treatment of cases o infection. Within its 888 pages will be found adequate information regarding the structure and life history of the variou animal parasites which assail man and the arthropod vector responsible for the transmission of many of them. The subject matter is clearly set forth, a notable feature being a series o tables giving at a glance the distribution of the parasites, thei localization in the body, the symptoms produced by them, th method of their transmission, the remedies to be employed fo their eradication, and other information.

The book is profusely illustrated with drawings which ar admittedly schematic but which depict the essential feature of each parasite or arthropod described, and by their excellenc render identification much simpler than it otherwise would be There are four coloured plates of intestinal protozoal cyst stained by iodine and of malarial and other blood parasite coloured by Leishman stain.

After an introduction (70 pages) dealing with such subject as nomenclature, evolution of animal parasites, hosts o parasites, pathological changes brought about by infection immunity, serological methods of diagnosis, treatment of parasitic diseases, and other general matters, a series of chapter (151 pages) describe the protozoa which may give rise t human infections. There then follow 21 chapters (366 pages on the helminthic parasites and 14 chapters (180 pages) o entomology. These chapters are distributed among a serie of six sections, and a final section deals with technical method for the diagnosis of parasitic infections and the chief drug employed in their treatment. References to relevant literatur are given throughout the book, while a good index enable any desired subject to be quickly turned up.

The book is comprehensive and reliable. It is unquestionabl a good one, and will prove to be of the greatest use to student of parasitology and an invaluable book of reference i laboratories which have to deal with the animal parasites o man and the pathological conditions they produce. We ca thoroughly recommend it to students of tropical medicine an medical men and laboratory workers in this and other countries

INTESTINAL OBSTRUCTION

Intestinal Obstructions. A Physiological and Clinical Consideration with Emphasis on Therapy, Including Description of Operative Procedures. By Owen H. Wangensteen, M.D. Second edition. (Pp. 484; illustrated. $7.00 post paid, or 38s. 6d.) Springfield and Baltimore: Charles C. Thomas; London: Baillière, Tindall and Cox. 1942.

Treves once wrote, "Those who are enamoured of statistic could, I have little doubt, show that it is less dangerous t leap from the Clifton Suspension Bridge, than to suffer fro acute intestinal obstruction and decline operation." If thi statement requires some modification to-day it is largely because of the present practice of intestinal decompression by suction following duodenal intubation. It is no longer true to say that high intestinal obstructions are more dangerous than low. The replacement of fluid and electrolyte loss, and duodenal tube drainage, have altered all that. In the introduction and development of duodenal suction drainage the author of this book has played a large part, for it was in 1931 that he first practised the procedure in the case of a patient aged 72 who had been obstructed for three days. Among much valuable experimental work relating to intestinal obstruction which Dr. Wangensteen has carried out since must be included his demonstration of the value of suction over mere siphonage. Adhesive obstructions are to-day especially amenable to treatment by conservative decompression, which in many cases brings about an automatic re-establishment of intestinal continuity; but Dr. Wangensteen insists that if a patient with mechanical obstruction is thus treated conservatively the progress of the decompression must be followed by *x*-ray films, because clinical data alone are insufficient evidence. With the advent of duodenal suction also the dread prospect of post-operative acute gastric dilatation ceases to disturb the surgeon. For this and many other benefits which duodenal suction has conferred we are grateful to the author of this monograph. We are further grateful for his production of the book itself, and now particularly of the second edition. It is in many respects a new book as compared with the original work, which consisted of the published winning essay for the Samuel D. Gross Prize of the Philadelphia Academy of Surgery for 1935. The Miller-Abbott tube, which appeared after the issue of the first edition, is adequately dealt with in the present edition, which contains much new matter.

This is probably the most complete treatise on the subject of intestinal obstruction that has yet appeared. Some idea of its scope may be gathered from the fact that it is arranged in four sections, the first being devoted to physiological and clinical aspects, the second dealing with diagnosis, the third with treatment and management of cases, and the last part with a consideration of the special obstructions such as congenital and obturator lesions, adhesions, tumours, herniae, intussusception, and obstructions due to vascular causes. Authors and subjects are indexed separately; illustrations and printing are good. We predict that the work will become a classic.

INDUSTRIAL HEALTH

Health Services in Industry. (Pp. 60. 2s. 6d.) Industrial Welfare Society, 14, Hobart Place, London, S.W.1.

The Industrial Welfare Society, which exists primarily as an information and propaganda medium for employers, has published an interesting booklet on health services in industry. The contents include reasons for the need for this service and how to set it up, staff and accommodation required, the position and duties of the medical officer and his relation with outside health services, records, ancillary services such as dental and ophthalmic, and a short final chapter on general health and working conditions.

While this booklet contains much useful information for the employer who is interested in the problem, there are certain statements which need comment. Stress is laid, for example, on the importance of rest rooms in factory medical departments. In our view they lead to abuse just because they are called rest rooms; rest is obviously part of treatment, but why not call it treatment? The suggested layouts for health service departments given in an appendix are hardly up to modern standards. The importance of medical examination of new entrants to industry is emphasized and taken for granted rather than considered critically on its merits in relation to labour turnover and present-day conditions of employment. Except for specific occupations, many hours can be wasted in wartime in carrying out such examinations as a routine, not only because of the labour position generally but also because of the lack of physical standards and the large margin of error in one medical opinion. The use of foot baths for shock will be a form of treatment new to many surgeons. The important fact, in relation to the prevention of sepsis, that exemption from the duty to provide first-aid boxes can be obtained from the factory inspectorate in factories with approved ambulance rooms is not mentioned. Beyond the need for light work and rehabilitation facilities for fracture cases there might have been some mention of the even greater need for organized treatment and rehabilitation services for other types of injury, which in factories outnumber fractures by 10 to 1. In connexion with sickness absenteeism we would have liked to see some practical suggestions on how the factory doctor could apply statistics in an attempt to reduce its incidence—for example, what should be his approach to the problem where he finds a high rate in a certain department or occupational group?

On the whole, however, the booklet contains much interesting information and should be read by all industrial medical officers. It is gratifying to know that the Industrial Welfare Society is still pressing actively for an extension of medical supervision in industry; its pioneer work in this direction is well known and must be fully acknowledged by the medical profession.

Notes on Books

Minor Surgery, by Dr. CHARLES M. OMAN, is another member of the Oxford Medical Outline Series (12s. 6d. each) and consists of pages of headings and rather terse comments interleaved with blanks, presumably for the student's remarks. The author tells us that it must not be forgotten that all minor surgery is potentially major surgery, and the inclusion in this book of such conditions as gas gangrene, acute osteomyelitis, abdominal injury, and compound fractures gives ample ground for his remark. As an example of the "make-up" we may quote from a comment on tourniquets (p. 145): "B. General consideration as to their use: 1. Frequently they are less necessary than is imagined." Most of us would agree with that. This little book covers the subject well and should be of service to students, provided they remember, as its author points out, that it has no pretence to being a textbook but is merely a practical working guide. Its chief use will obviously be in the casualty and out-patient departments and wards, and full use should be made of the blank sheets for amplification and notes of cases.

The seventh edition of the popular textbook *Diseases of Women,* by Ten Teachers (Edward Arnold; 18s.), is a good one and, like its companion volume on midwifery, it has been completely revised. With the advent of specific chemotherapy it has been found necessary to rewrite those sections dealing with pelvic inflammation. General principles more than details of treatment are discussed throughout the book. The student is thus given a concise guide to his studies rather than an exhaustive textbook of reference.

The great popularity among students of Dr. R. W. FAIRBROTHER'S *Text-book of Bacteriology* (William Heinemann; 17s. 6d.) is shown by the publication of a fourth edition only five years after its original appearance: each of the earlier editions also had to be reprinted. The principal change made is the addition of a new chapter on chemotherapy.

The late Mrs. J. LANGTON HEWER'S popular handbook *Our Baby for Mothers and Nurses* has now reached a 22nd edition and 213th thousand since its first appearance half a century ago. The text has been revised from the medical point of view by Dr. Margaret Scott-Brown, who has made it her aim to leave Mrs. Hewer's fundamental teaching unaltered. The publishers are John Wright and Sons, Ltd., and the price is 5s.

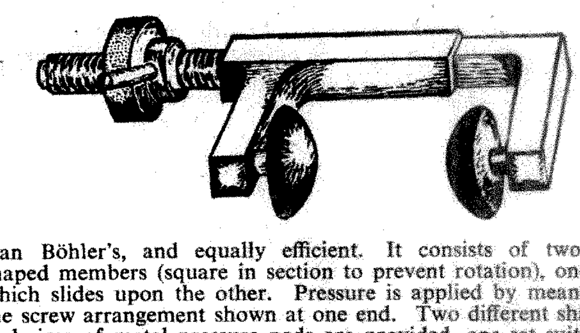
A pamphlet that will be useful to many general practitioners is *War-time Information for Pharmacists* compiled by the *Pharmaceutical Journal* and published by the Pharmaceutical Press (17, Bloomsbury Square, W.C.1) at 1s. The contents are arranged in the alphabetical order of their headings and there is a convenient list of addresses at the end.

Preparations and Appliances

A SIMPLE FRACTURE REDRESSOR

Major G. A. G. Mitchell, R.A.M.C., O.C. No. 1 Orthopaedic Centre, M.E.F., writes:

Crush fractures of the tibial head and os calcis are common results of land and sea mine explosions and of aeroplane and parachute accidents. Manual reduction of these injuries is often difficult, and then a redressor is valuable. The instrument illustrated in the line drawing (1/4 scale) is simpler in design than Böhler's, and equally efficient. It consists of two L-shaped members (square in section to prevent rotation), one of which slides upon the other. Pressure is applied by means of the screw arrangement shown at one end. Two different shapes and sizes of metal pressure pads are provided, one set suitable for the os calcis and the other for the tibial head; they are supported on short columns with screw ends, so that they are easily interchangeable. The original instrument was made for me in an R.A.O.C. workshop.



THE STUDY OF NUTRITION IN LATIN AMERICA

BY

PEDRO ALBERTO ESCUDERO, M.D.
Assistant Chief, Nutrition Department, National School for Dietitians, Buenos Aires

(ABRIDGED)

The National Institute of Nutrition at Buenos Aires has come about as a gradual development over a period of ten years. In 1921 Prof. P. Escudero,* professor of clinical medicine at the National University, started a scientific movement for the study of nutrition. Three years later he suggested to the Director of Public Assistance the desirability of a survey of nutritional diseases, to be carried out at the Rawson Hospital. The services so created were the origin of the Municipal Institute of Nutrition in 1928, at which systematized studies were undertaken. Here the first dietetic kitchen in Argentina was established. A survey of nutrition was made at the municipal hospitals in 1931 under the guidance of Prof. Escudero, and its results were summarized in a report to the fourth National Congress of Medicine in Argentina.

A School of Dietitians was started in 1935; and in 1938, by a decree of the then President, General Justo, the National Institute of Nutrition was founded. This included the School of Dietitians and also a residential college for students from the provinces and territories, whereby the benefits of the foundation were extended to the interior of the country. To enter the Institute the candidate must show the same standard of secondary education as is required for entrance to the Medical Faculty. Almost every province and national territory now has graduates from the Institute. In 1939 scholarships were instituted to promote the study of dietetics as a medical specialty, and during the present year doctors from four provinces have graduated. In the course of the next decade or two it is expected that a considerable number of medical specialists in nutrition will be practising in the country.

The third International Conference on Nutrition under the auspices of the League of Nations—the first to be held outside Geneva—assembled at Buenos Aires in 1939, and its conclusions were so startling that in October of that year the late President of the Republic, Dr. Ortiz, opened the doors of the Institute to all Latin-American countries, with a grant of scholarships for dietitians and dietetic specialists. Fellows from six South American countries apart from Argentina itself have now graduated from or are students at the Institute. Thus the Institute has become a Latin-American university centre for the study of nutrition. It has a staff of over 300, and its present provisional budget is for 1,200,000 pesos (about £70,000). An Act conferring full autonomy on the Institute and providing for its resources is expected shortly to be passed by the Argentine Senate.

Aims of the Institute of Nutrition

Prof. Escudero has given the following definition of the work of his Institute: "The basis for the conservation of the human being is nutrition; life, strength, reproduction, mental energy, and social and moral progress are dependent upon it. The Institute of Nutrition includes the study both of the life of the individual as a physical and moral entity and of the society of which he forms a part. The Institute is not merely a hospital, although it treats patients; not merely a laboratory, although it examines biological processes; not merely a centre for social studies, although it investigates sociological phenomena; not merely an office for social welfare, although it helps those in need; nor is it merely a school or a pulpit, although it teaches and preaches. It is all these things, with investigation of facts, causes, and remedies as its central aim." In other words, it is a centre for social, economic, and hygienic survey. It co-ordinates all these branches of activity with a view to maintaining and improving the physical and moral health of the individual, the family, and the community. In studying the patient and the causes of disease it has always the prophylactic aim in view.

In many quarters there exists a narrow and therefore mistaken notion of what is understood by nutrition. The Director of the Institute divides nutrition into three stages: (1) alimentation, or intake of matter and energy, beginning from the time the food is chosen; (2) metabolism, or exchange of matter and of energy, beginning from the moment of absorption of the alimentary substance; (3) excretion, or the elimination of the used or unusable. Nutrition, he says, is not a single function, but the result of correctly harmonized functions which complement one another, and the aim is to maintain the normal integrity of living matter and to ensure life. Too often nutrition is considered only as metabolism. Prof. Escudero has similarly enlarged the notion of nutritional disease, which to most authors is a synonym for metabolic disorder. He divides all nutritional diseases into three main groups: alimentary, metabolic, and excretory.

Some special forms of study and of approach to the subject have been adopted at the Institute. One of these is "alimentary anamnesis"—to assist in the judgment of the existing alimentation and to furnish information of the effect of past and present dietary habits on the disease or the state of the patient. A formulary has been worked out for the examination and comparison of different dietaries so that adjustments can be made and prescriptions given for the food required and the way it should be prepared and consumed. By these various methods and formularies it is possible to prescribe, examine, and compare the diets advised.

Character of the Studies

In its studies the Institute works in six divisions, co-ordinated by a general direction. These divisions are: education, social work, alimentation, research, educational work, and medical assistance. The general direction undertakes the administrative and technical control of the Institute, which has a general and a technical secretary. The problems which come before the general direction can be divided into three—health, economic, and social—always, of course, related to nutrition. For the solution of such problems a technical council or board is formed by the heads of the divisions, with the general director as chairman.

The educational division is concerned with the training of technicians in food and alimentation. The teaching of this discipline is officially assigned to the Institute by the Faculty of Medicine of the University, and there is perfect understanding between the two bodies, as the General Director of the Institute is also Professor of Nutrition. Training is given in the Nutrition Clinic for undergraduates of the School of Medicine in their final year (the seventh), also finishing courses for graduates who are to become dietitians, a title awarded by the Faculty. By decree of the National Executive Board all official technical posts related to food and alimentation must be preferentially filled by those who have followed these courses. The students are first instructed in the alimentation of the normal individual and the community and afterwards in the alimentation of sick persons.

The training of dietitians is of a university type, claimed to be far superior to the similar disciplines at other American and at European schools. The plan of studies is divided into two cycles. The first includes normal alimentation from the biological and economic points of view for the individual at different ages and for the community; the second considers alimentation in sickness. Two scholastic years are occupied with the first—or normal—studies, and the third with alimentation in disease. For admission to this training a college course degree is required, such as Bachelorship of Arts or Commerce. The occupation of dietitian (non-medical) is reserved to women.

The School also trains auxiliaries and nurses specializing in food problems; the studies undertaken in these cases are more restricted. The medical dietetic specialist, the dietitian, and their co-workers—the auxiliary and the nurse—form a unit ready to solve any nutritional problems. As already stated the School has a residential quarter where students from the provinces or from other Latin-American countries may be boarded during their training.

Sociological Studies

The division of the Institute which deals with social work is subdivided into research, prevention, and social assistance sections. The research section has two branches, one of which is concerned with the social and economic condition of the families investigated, making inquiries regarding income, food consumption, and health conditions; the other branch is concerned with the moral condition of families through a survey of social behaviour and mental health.

The section dealing with prevention is entrusted with the care and protection of normal individuals. It has nothing in common with the so-called health centres in other countries. Its work is carried out by means of clinics or consultations at which advice is given on matters of health, food, and the influence of work and home in relation to the age and condition of the individual. Periodical examinations are made, patients being given appointments at the day and hour most suitable to them. Food is studied from the hygienic and economic points of view, and advice is given regarding the best kinds of food to choose, bearing in mind the family budget and the individual requirements. Eugenics, care and protection of pregnant women and nursing mothers, care of children, popular education on food questions, and social records, all come within the scope of this section.

In the section of social assistance various moral problems and problems of behaviour concerning the individual and the family come forward for consideration. Occupation is provided for the workless, and material help, mainly in the form of food, is also provided. In this connexion the Institute endeavours to preserve family life. It does not rely on popular restaurants or canteens, which disturb the normal family relations. The meal-time is the occasion for the gathering of the family, the time when the existence of the family as a unit is best manifested. The provision of canteens is accepted as a necessary accompaniment of industrial or business life, but it is not regarded as anything like the ideal approach to the nutritional problem. A more discriminating assistance is sought to be given, requiring knowledge of the family and its means, and calling for the teaching of cooking and the best means of utilizing food, and in necessitous cases the giving of foodstuffs.

Help is still more generous in the case of pregnant or nursing women and mothers of small children. A lactarium for the free provision of mothers' milk, regardless of the family budget, for the first month of the infant's life, has been set up, and so far has proved extremely successful. The extra milk is purchased from the donor mothers, and both their babies and those of the receiving mothers are supervised.

Alimentation, Research, and Propaganda

The alimentation division of the Institute includes various technical studies, and maintains and controls free refectories for sick people and school canteens; dietetic restaurants, too, are shortly to be provided for sick persons who can afford to pay. The work of the division is undertaken by a number of medical dietetic specialists, lay dietitians, auxiliaries, and nurses. The research division includes various chemical and biological laboratories; laboratories of alimentary technology and an experimental farm are projected.

In the sphere of propaganda one division undertakes the service of the Press and wireless to popularize basic knowledge about nutrition. Lectures are given to teachers and to housewives on kitchen cookery and on the best utilization of the food they purchase, with brief explanations of the hygiene of alimentation. These lectures and courses are given by women dietitians who are well acquainted with this kind of social and educational work.

Finally, a sixth division undertakes medical assistance in nutritional diseases. It is estimated that 80% of such chronic patients do not require complete institutional treatment. They can be assisted as out-patients by means of a refectory, receiving, in fact, everything that they would have received in an institution except the bed. The patient sleeps at home, carries on his work, and has his meals at the Institute. The acute cases or cases in the acute stage of a chronic condition are received at a residence having 60 beds, to which also are admitted cases requiring special study. Usually the patients who need a special diet and have their meals at the refectory are suffering from diseases of metabolism and imbalance, diseases of the digestive tract and its glands, of the urinary and renal system, and of the skin. The assistance given is supplemented by the service of consultants in dermatology, gynaecology, urinary diseases, and otology and laryngology. Physiotherapy and massage are administered. There are also a small surgical service, a radiological department, and pathological laboratories.

The service given to in-patients and out-patients extends to all ages and both sexes, and is organized on the lines of a general hospital. Between 6,500 and 7,000 patients are treated every year.

Future Work of the Institute

It should be borne in mind, however, that the Institute is principally a centre of investigation and teaching. The direct assistance given to patients is only of limited extent; the aim of the Institute is to ascertain the best form of assistance, not to fulfil it as a routine. The same is true of the social assistance which it affords. It avoids mere extension due to the multiplication of the routine of its services; it looks for the cause of the phenomena studied and endeavours to find the remedy or the means of avoiding them.

Its social and educational work is equally important. Until 1921 studies on nutrition were regarded with indifference by the scientific world of Argentina. Until 1930 the Government, the Legislature, and the people were generally ignorant of alimentary problems, although the main source of the revenue of the country is food production. But the question of popular alimentation has awakened a legislative, social, and economic movement, the more marked since the third International Conference on Nutrition under the auspices of the League of Nations was held at Buenos Aires in 1939.

Over a period of eighteen months—from June, 1936, to November, 1937—the Institute conducted a survey of health conditions in Buenos Aires in relation to the family budget. The expenditure on food and the minimum budget required to live modestly but decently and to be correctly fed were estimated. A similar survey has just been completed at the industrial town of Avellaneda, a suburb of Buenos Aires, and another is being carried out at the town of Mendoza. Prof. Escudero resigned his professorship of clinical medicine, which he had held since 1921, to become professor of nutrition when the Faculty of Medicine included a clinic of nutrition in its plan of studies.

The work already done in the training of medical dietologists, dietitians—a new profession which may be said to have been created by the Institute—and their auxiliaries is expected to have further developments in the Argentine Republic. Already the province of Mendoza in Western Argentina has set up a department of nutrition as a branch of its health direction, involving a certain modification of its hospitals and an economic-social survey of its population. The Institute has also started to draw up an "alimentary geography" of the country, including a study of alimentary folklore and of present food production. By the time the work of the Institute reaches its full development it is hoped that health conditions in Argentina will have manifested very great improvement owing to a recognition of what the founder of the Institute has called the "non-specific prophylaxis" of diseases whose onset is due to simple maladjustments in living rather than to any specific cause.

H. P. Fernandez (*Tubercle*, 1942, 23, 50) records six cases in patients aged from 20 to 39 who developed symptoms of distress after aspiration. The onset of these symptoms was attended by a fall in blood pressure, associated with high negative intrapleural pressures, mediastinal displacement, and lung re-expansion. In all cases relief of distress followed injection of adrenaline and pituitrin. The relief was accompanied by a rise in blood pressure and occurred at a time when mediastinal displacement, lung re-expansion, and high negative intrapleural pressure had not been adjusted. Fernandez comes to the following conclusions: (1) The symptoms of distress after aspiration were due to a high negative intrapleural pressure; lung re-expansion produced by this led to a circulatory disturbance, causing a fall in blood pressure. (2) Injection of adrenaline is of value as an emergency measure for such distress.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY DECEMBER 12 1942

THE BEVERIDGE PLAN

The publication on December 2 of Sir William Beveridge's Report on Social Insurance and Allied Services had not been unheralded in the Press, and many intelligent anticipations reached the public eye before the large printed document was released. The report has been widely summarized and commented upon in newspapers and reviews during the past ten days, and medical men and women must already be familiar with its broad outlines. Sir William Beveridge alone signs the report, though he acted as chairman of an interdepartmental committee set up to survey the whole field of existing national schemes of social insurance and allied services, including workmen's compensation. For the views and recommendations on questions of policy which the report contains Sir William, by the Government's wish, takes sole responsibility. His plan for post-war social security aims to replace the present medley of social services by a single comprehensive system, bringing the adult population of the country into a compulsory, and in the main contributory, unified scheme of insurance to provide against sickness and unemployment and old age, and for family allowances. It is meant to include all citizens, without upper income limit, and to be administered by a new Ministry of National Security, to which would be transferred the relative responsibilities of six or more Government Departments as well as some of the duties of local authorities. One stamp on one insurance document, payable weekly, would cover all social insurance schemes.

Briefly put, the report proposes that medical treatment should be separated from the administration of cash benefits and that a comprehensive medical service should be set up for everyone, covering all treatment and every form of disability, under the supervision of the Health Departments. The paragraphs which are of primary interest to the medical profession and those associated with it have so far had little attention in the newspapers, and for that reason we print them in full at p. 704. Sir William Beveridge accepts the view that restoration of a sick person to health is a duty of the State and of the sick person, prior to any other consideration; and he adopts the definition of the objects of medical service in the draft interim report of the Medical Planning Commission of the B.M.A. —"(*a*) To provide a system of medical service directed towards the achievement of positive health, of the prevention of disease, and the relief of sickness; (*b*) to render available to every individual all necessary medical services, both general and specialized, and both domiciliary and institutional." But he says that most of the problems of organization of such a service fall outside the scope of his report. This excludes any opinion by him on such questions as free choice of doctor, group or individual practice, or the place of voluntary and public hospitals respectively in a national scheme. "Once it is accepted that the administration of medical practice shall be lifted out of social insurance to become part of a comprehensive health service, the questions that remain for answer in this report are in the main financial." It will be seen that in handling these financial questions, after dismissing organization as no affair of his, he takes up in separate paragraphs domiciliary treatment, institutional treatment, special services like dental and ophthalmic treatment, subsidiary services such as supply of medical or surgical appliances, nursing and convalescent homes, and post-medical rehabilitation.

The problems involved in establishing and running a comprehensive medical service for all, and even the financial basis of such a service, are excluded from the Beveridge Report. Its author merely suggests the need for a further immediate investigation in which the finance and the organization of medical services could be considered together, in consultation with the professions concerned and with the public and voluntary organizations which have established hospitals and other institutions. The ideal plan, in his view, is a health service providing full preventive and curative treatment of every kind for every citizen without exceptions, without income limit, and without an economic barrier at any point to delay recourse to it—in other words, a 100% service for 100% of the population. His cool words about the effect of all this on private medical practice will arouse mixed feelings: "The possible scope of private general practice will be so restricted that it may not appear worth while to preserve it." Further immediate investigation is certainly called for, and it will have to be very thorough. The primary interest of the proposed Ministry of National Security may not be in the details of the national health service or in its financial arrangements; but such details and arrangements must be worked out with the full consent of those who provide the service if the great social plan of which they will form part is to fulfil its author's great expectations.

PREVENTION AND TREATMENT OF HEPATITIS

A rise in the jaundice rate seems to be an inevitable concomitant of war, and this war has been no exception to the rule. Epidemics of infective hepatitis have been reported by the enemy and have occurred among our own troops. The increase in the incidence of syphilis and in the vigour of arsenical treatment has its corollary in the increase of toxic jaundice. Our American allies have had the unfortunate experience of a high incidence of jaundice after vaccination against yellow fever, now happily arrested by improvements in the vaccine. On a very much smaller scale there has been the usual outbreak of T.N.T. jaundice which follows the entry of an unsalted population into the filling factories. Most cases of non-obstructive jaundice clear up rapidly, but when the jaundice lingers or recurs the physician's anxiety deepens, for experience shows that fibrosis or insufficiency of the liver is inevitable if the disease process is not arrested. We may well ask ourselves why inflammation or degeneration persists when the initial noxa has presumably disappeared. Cullinan[1] found final degeneration of the regenerated liver tissue in all but two of his cases of recurrent jaundice, and in some there was evidence of at least three attacks of necrosis. Is there a vicious circle, comparable with that in Bright's disease,[2] so that the metabolism now perpetuates some harmful product or process? Our thoughts turn to a diet which will spare the damaged liver, in the same way that undernutrition will arrest the progress of diabetes. When we consult textbooks on treatment we are advised that the diet should be chiefly carbohydrate in composition as throwing least strain on the damaged organ. "Proteins should be kept down to the minimum bodily requirement, as the metabolism of their derivatives requires hepatic activity."[3] Experimental work carried out from a variety of aspects shows that, while restriction of fat is indeed essential in conditions of strain or damage to the liver, restriction of protein is not merely unnecessary but positively harmful.

---

[1] *St. Bart's Hosp. Rep.*, 1936, **69**, 55

[2] *Quart. J. Med.*, 1941, **10**, 65.

Best[4] has summarized the work on fatty degeneration of the liver which has grown out of the original discovery of insulin. Depancreatized dogs which are kept alive by insulin eventually develop large fatty livers. The fatty degeneration of the liver can be prevented by feeding the dogs with raw beef pancreas. Successive discoveries showed that the same curative effect was exerted by lecithin (which is a compound of fat, phosphoric acid, and choline) and by choline alone. It is now clear that choline accelerates the formation of phospholipids and the turnover of fat in the liver. Most of the recent work has been done on white rats, which develop fatty livers and eventually cirrhosis when they are fed on diets very rich in fat. Fatty degeneration can be prevented not only by choline but also by casein, methionine, and the choline-like amine, betaine. These observations have given rise to the hypothesis that the protein (casein) acts by virtue of its amino-acid (methionine), which provides the labile methyl groups out of which choline is built up and which are essential for the orderly metabolism of fat in the liver. The type of fatty liver upon which these substances act specifically is that due to relative or absolute deficiency of choline, but it has also been shown that choline accelerates the disappearance of fat from a liver which has been poisoned by phosphorus or carbon tetrachloride. A second important factor for the integrity of the liver is an unidentified component of the vitamin B complex which is present in yeast. Degenerative changes develop in the livers of rats and rabbits fed on diets which are deficient in vitamin B, but they can be prevented by the addition of yeast extract. Moreover, yeast diminishes or prevents the liver damage caused by arsenic, "butter yellow," and high fat diets. Webster[5] has found indications that molasses may have a like protective action. Whipple,[6] who approached the problem in relation to hypoproteinaemia, has shown that the dog whose plasma has been depleted by repeated removal of plasma protein is very susceptible to intoxication by drugs such as chloroform and arsenicals. This susceptibility can be promptly removed by large protein feedings or considerable amounts of plasma given by vein. Further, methionine will protect the plasma-depleted dog against chloroform anaesthesia, though other amino-acids which do not contain sulphur are inert in similar experiments. Lecithin and choline are likewise inactive. The mechanism of action of methionine therefore differs in hypoproteinaemia and in overfeeding of fat, and methionine is evidently a key substance in the metabolism of the liver.

It would seem rational to apply these experimental data to the prevention and treatment of hepatitis in man. Diets should be low in fat and high in protein and carbohydrate. The construction of such a diet is not altogether easy, for many protein foods, such as meat, eggs, and cheese, are relatively rich in fat. Vegetable protein, which is easier to secure in wartime than animal protein, has been regarded as particularly suitable for disease of the liver. A useful ingredient in this country is skimmed milk, whole or dried, which is in fairly free supply at the present time and which contains the valuable protein casein. With this it is not difficult for the dietitian to devise diets containing approximately 100 g. protein, as little as 20 g. fat, and enough carbohydrate to supply the necessary calories. As the fats are reduced, it is wise to administer concentrates of fat-soluble vitamins A and D, and vitamin K if there is evidence of prothrombin deficiency. Hypoproteinaemia should be corrected by transfusion of plasma. Baker's yeast should be prescribed, and increased, if tolerated, from 3 teaspoonfuls to 1 to 3 oz. a day. Molasses is harder to come by, but a not unpleasant drink can be concocted on a basis of yeast and molasses. Such a drink might be offered as an alternative to the draught of magnesium sulphate which is so popular with workers going on duty on the T.N.T. plants in some of the Royal Ordnance Factories. Pure amino-acids are expensive, and they are not always tolerated well by mouth. No information is available about the use of methionine in man, but favourable results have been reported[7] from the administration of choline chloride in a dose of 1 g. daily in cirrhosis of the liver, together with a diet like that outlined above.

RHYTHM OF THE FEMALE SEX CYCLE

It has been generally believed by endocrinologists that the rhythmic nature of the sexual processes in the uterus and vagina could be explained by the interrelation of pituitary and ovarian secretions. The growth of the ovarian follicles is under the control of a follicle-stimulating pituitary hormone. The fluid formed in the growing follicles is rich in oestrogen. Oestrogens in excess depress pituitary function but first appear to stimulate production of the pituitary luteinizing hormone. There is experimental evidence for all the above statements, and if we assume that the corpora lutea produce less oestrogen, so allowing the secretion of follicle-stimulating hormone to begin again, we have gone a long way to unravel the mechanism of the ovarian cycle: the oestral and menstrual cycles in the lower and higher vertebrates were assumed to be a reflection of this ovarian cycle. Some years ago, however, Zuckerman[8] observed that regular cyclic uterine bleeding was induced in an ovariectomized monkey by the injection of a constant daily dose of oestrone. The dose had to be carefully adjusted: with too much oestrone no bleeding occurred until some time after stopping the injections (oestrone-withdrawal bleeding); if too little were given there was no bleeding at all. Zuckerman[9] has lately confirmed his original finding in a group of 15 ovariectomized Rhesus monkeys, 10 of which experienced periodic uterine bleeding when injected daily with a constant threshold dose of oestrone; the average length of time between successive bleedings in 68 of these "artificial threshold cycles" was 43 days, which did not differ significantly from the length of the normal menstrual cycle in a control series collected by Corner,[10] though somewhat longer than that of a larger control series collected by Zuckerman himself.[11] Similar threshold oestrous cycles have been observed in rats injected daily with an appropriate dose of oestrone[12] and the length of the cycles shown to be the same as that of normal oestrous cycles in intact rats.[13] These facts clearly demonstrate that a fluctuating secretion of oestrogen by the ovary is not essential to explain the cyclic changes in the uterus and vagina.

Last year Bourne and Zuckerman,[14] in a more extensive study of these artificial cycles, found that they could still be produced in hypophysectomized ovariectomized rats, but were elicited only rarely in the absence of the adrenal glands, even though the rats were given daily injections of desoxycorticosterone which kept them alive and allowed the continuance of the oestrous cycle in adrenalectomized rats with intact ovaries. They concluded that the rhythmic nature of the vaginal changes was determined by the adrenals. They then[15] investigated the adrenal glands during normal and artificial oestrous cycles. Painstaking histological examinations and measurements were made of glands removed in the oestrous and di-oestrous phases of the cycles and the results compared statistically. These statistics are too detailed for analysis here, but the following main facts emerged. In both normal and artificial threshold cycles the adrenal glands were heavier and bulkier during oestrus than during di-oestrus. These fluctuations were practically confined to the cortex of the gland, and within the cortex it was the zona fasciculata that was chiefly affected. The alterations in volume of this zone were brought about by changes in the size of the cells and not in their number. It was also found that these adrenal fluctuations were present during artificial oestrous cycles produced in rats with both hypophysis and ovaries removed. All of this is strong corroborative evidence for the essential role of the adrenals in causing cyclic changes in the accessory sex organs. How it brings these effects about is a matter for speculation. The authors offer three possible explanations: first, the adrenals may induce cyclic hydration and dehydration of the reproductive tract with consequent variations in sensitivity; secondly, their known production of oestrogen may be cyclic and subthreshold, reaching threshold levels only when supplemented from some other source; or, thirdly, the glands may yield fluctuating amounts of anti-oestrogenic substances such as androgens or progesterone. It will be seen that all these explanations shirk the problem of explaining the cyclical nature of the effects. A cycle produced by the combined co-operation and antagonism of pituitary and ovarian secretion could be visualized, but on the available evidence the adrenal appears to be intrinsically cyclic, which, if it is true, is much more difficult to comprehend. A menstruation centre in the hypothalamus has been postulated[16]—perhaps there is a hypothalamic–adrenal relation similar in some ways to the pituitary–ovarian one.

TOURNIQUET FOR HEART FAILURE

The application of venous tourniquets to the limbs has been practised instead of venesection in cases of heart failure for a number of years since its introduction by Danzer in 1928 The peripheral venous bed is turned into a reservoir in which may be stored about 12 to 15% of the circulating blood volume. The method was shown to be effective in the treatment of left ventricular failure by Weiss and Robb in 1933. An interesting light is thrown on its mechanism by Kountz, Smith, and Wright,[17] who used a machine which maintained inflation of cuffs placed on all four limbs for four minutes and deflation for one minute, the latter so arranged as to operate on each limb in turn, so that three limbs were always congested. The authors found that cases of left ventricular failure responded very well, but that those with right ventricular failure, as in acute or chronic cor pulmonale, did not. The point of interest was this: while the venous pressure fell and kymographic pulsation of the heart diminished (the expected results of lessening the venous return), the size of the heart, as measured by its transverse diameter, increased appreciably in normal subjects and in two patients with mitral stenosis. Cases of left ventricular failure showed no such increase. On the contrary, two of them showed a smaller heart shadow during venous compression. No explanation of this phenomenon is available. Cardiac output was not measured; but as neither the pulse rate nor the blood pressure altered appreciably, whereas the venous pressure and amplitude of cardiac pulsation fell, it may be assumed that the cardiac output fell too. Before looking for the solution the facts should be confirmed, for very few cases seem to have been studied in this paper. However, the method of treating orthopnoea and paroxysmal cardiac dyspnoea by compression of the limb veins is again brought before the notice of physicians.

FAKED FITS AND ABSENT RECORDS

The winter session of the General Medical Council was remarkable for a number of cases in which complaints by the Ministry of Labour and National Service were lodged against doctors on the ground that they had given false or misleading certificates to enable young men to evade military service. The evidence threw light upon a grotesque system which has been in operation whereby men due for appearance before medical boards have been coached by some elusive person—sometimes a man and in other cases a woman—in the simulation of the symptoms of epilepsy. Under the guidance of this person, who posed as a relative, the Army-shy young man was made to sham fits, was then taken to a doctor, or sometimes a succession of doctors, and medical certificates were obtained which were in due course presented to the medical board and succeeded for a time in imposing on the authorities. Sums amounting to hundreds of pounds were mentioned in connexion with these frauds. One young man (who incidentally has since been discharged from the Army on account of osteomyelitis) confessed in the witness box that he had paid 350 guineas to his "aunt" who showed him how to convince doctors, not of his lameness, but of his long-standing epilepsy, a condition from which he had never suffered. A witness told the Council how he was instructed to behave—to stroke his nose in a certain way, to take a quantity of black coffee the night before and have very little sleep, and to try to bite his tongue. Even doctors such as those on medical boards—against whom, of course, there was no breath of suspicion—were impressed, and in certain cases, it was said, when the interesting "patient" arrived they did not allow him to get out of the car but came one by one and looked at him in the vehicle. A final touch was added to the situation by the fact that several of these young men held driving licences, and one of them, who had originally been put in Grade 4 as an epileptic, but was afterwards re-graded, stated that he was now in the Army as a motor-driver. Sometimes, however, the chief interest in a case which comes before the General Medical Council lies in some incidental revelation. In certain of these cases the astonishing thing was not so much the issue of wrongful certificates as the manner in which a large practice was conducted without any proper records even of medicines supplied, not to speak of clinical details. One of the respondent doctors, who stated that his practice brought him in over £3,000 a year, admitted in the witness box that, although for his private patients he did his own dispensing, he had kept no records whatever. Comment was made on the fact that he had given luminal and other drugs to the supposed epileptics mentioned in the charge (and he said that at the relevant time he had 20 or 30 people in his practice whom he was treating for epilepsy), but no note of this appeared in his books. The only entries relating to the cases were in his diaries, and these were merely records of fees paid or to be charged.

[17] *Amer. Heart J.* 1942, 23, 624.

Such absence of records is, of course, not a fault which brings a practitioner within the purview of the Council, but it is a highly questionable way of conducting a practice. It is disadvantageous to the patient who may present himself again for treatment after a lapse of time if the doctor has to rely solely on his memory as to the treatment given him on the previous occasion, and it may be damaging to the doctor himself if at some later date his treatment should be called in question. The excuses of a large and busy practice are of no avail; the larger the practice the more necessary it is, in the interests of good treatment, apart from any possible legal action, that the practitioner should fortify his memory by careful notes, whether the drugs are "dangerous" in the technical sense or not.

THE BLOOD–BRAIN BARRIER

The conception of a semi-permeable barrier between the blood and the brain dates back to the end of the last century, when it was found that certain substances such as trypan blue or diphtheria toxin failed to produce any change in the central nervous system (c.n.s.) on intravenous injection, while they were very active on intracerebral or intraventricular injection. In recent years there has been a growing interest in the practical application of this theory to medicine, and Friedemann[1] has summarized the present position. It should perhaps be emphasized that the blood–brain barrier is located in the capillary endothelium of the cerebral vessels, and that the cerebrospinal fluid plays no part in this connexion as an intermediary in the exchange of substances from blood to brain. The method of investigation may be illustrated by certain experiments on diphtheria toxin. It was found that the rat is almost immune to intravenous injection of this toxin while highly susceptible to intracerebral injection, which caused striking pathological changes; conversely, in rabbits the protecting dose of antitoxin is the same by the intravenous or the intracerebral route, although the toxin is 20 to 40 times more potent on intracerebral injection. These results suggest that the capillaries of the c.n.s. are relatively impermeable to diphtheria toxin, and so circulatory failure in the early stages of the infection, at least in animals, is probably not due to medullary paralysis. From similar experiments there is additional evidence that tetanus and botulinus toxins reach the c.n.s. by neural rather than by vascular pathways. Adrenaline caused a five- to ten-fold increase in the permeability of the cerebral capillaries to substances such as paraldehyde, strychnine, and ethyl urethane, to which they are already permeable. It was suggested that since adrenaline lowered the intravenous lethal dose of cobra venom for a rabbit from 0.5 mg. to 0.025–0.05 mg., the blood–brain barrier is therefore by analogy permeable to cobra venom. While this conclusion is not perhaps altogether justifiable, the observation is clearly of practical importance in so far as it can be applied to man. Friedemann also concluded that the blood–brain barrier was impermeable to the neurotropic viruses, such as those of poliomyelitis or rabies, which, like tetanus and botulinus toxins, must therefore reach the c.n.s. via the peripheral nerves. Experiments with tetanus and diphtheria antitoxins suggested that they could pass through the cerebral capillaries, but that the antitoxin concentration in the intercellular fluid was only 1/20 to 1/60 of that in the blood plasma. This observation is a further justification for the intrathecal administration of antitetanus serum in cases of tetanus, and explains the slow therapeutic response. Of the various drugs which act on the c.n.s. it was observed that many may act indirectly, as, for instance, by stimulating the carotid sinus. To be sure that they penetrate the blood–brain barrier it is necessary to identify them in the brain after intravenous injection. In this way it has been shown that many alkaloids and the sulphonamides pass the cerebral capillaries, while neoarsphenamine and suramin (Bayer 205) do not.

Friedemann concludes from the large number of observations on this subject that the ability of substances to pass the capillaries of the c.n.s. is determined by their electrochemical properties. So the higher permeability of the blood–brain barrier to electropositive substances may explain the rapid action of cobra venom in contradistinction to the slow action of tetanus and botulinus toxins, which have to make their way along the peripheral nerves into the c.n.s. rather than via the blood stream.

TANNIC ACID, BURNS, AND THE LIVER

The tannic acid treatment of burns has by many been criticized and by some condemned on account of its local effects, especially when used on the hands and face. Its most violent critics, however, seldom disputed its value as a life-saving measure in extensive burns of the trunk and limbs, although convincing statistical evidence of its superiority over other methods has not been produced. Now comes evidence from America imputing to tannic acid a toxic effect on the liver which may kill the patient. Wells, Humphrey, and Coll[1] report 4 fatal cases of burns in which death was attributed in whole or part to liver necrosis. Suspecting that tannic acid was to blame, they experimented on rats, and by subcutaneous injection of tannic acid produced liver necrosis similar to that found in the fatal burns—the degree of necrosis being proportionate to the dose of tannic acid. The necrosis affects the central part of the liver lobule and is identical with that described by Wilson and his co-workers as being the characteristic lesion of burn toxaemia. It would be premature to conclude that burn toxaemia is tannic acid poisoning, but that is the suggested implication, and other agents such as silver nitrate should be employed by those who hold that coagulation is a desirable part of burn therapy.

One of the advantages claimed for coagulation is control of fluid loss, and with tannic acid now suspect as a poison other methods of achieving this end assume greater interest and importance. Siler and Reid[2] report 134 cases treated by Koch's "primary cleansing, compression, and rest treatment of burns" and claim good results. About a third of the burns were extensive, and only 5 patients died. These workers tried to show by experiments on dogs that the method of pressure dressing controls haemoconcentration and loss of plasma protein, but although their results were suggestive of a beneficial effect they were not statistically significant.

A second advantage claimed for tanning is the control of infection. This end may be attained with more certainty by sulphonamides and/or other agents such as C.T.A.B. In the series reported by Siler and Reid only one patient died of sepsis and in none were sulphonamides used, but meticulous primary cleansing is an essential part of the Koch method. Although tannic acid is suspect as a poison, a comment of Wells is worthy of note, that he would be unwilling to give up a method that has proved so beneficial, even if it did cause an occasional death. But if other agents will produce an equally beneficial coagulation it would seem wise to avoid tannic acid until it has been cleared of suspicion.

SOCIAL INSURANCE AND SERVICES

MEDICAL PARTS OF THE BEVERIDGE PLAN

The proposals in Sir William Beveridge's Report on Social Insurance and Allied Services* which are of most immediate importance to the medical profession are conveniently summarized in three paragraphs taken from different sections of the report. First, among the main provisions of the Plan for Social Security is the following:

"Medical treatment covering all requirements will be provided for all citizens by a national health service organized under the Health Departments, and medical rehabilitation treatment will be provided for all persons capable of profiting by it."

Second, among the principal changes from present practice that the author considers will be necessary is:

"Separation of medical treatment from the administration of cash benefits and the setting up of a comprehensive medical service for every citizen, covering all treatment and every form of disability, under the supervision of the Health Departments."

Third, the report states that no satisfactory scheme of social security can be devised except on the following assumptions:

(A) Children's allowances for children up to the age of 15, or if in full-time education up to the age of 16;

(B) Comprehensive health and rehabilitation services for prevention and cure of disease and restoration of capacity for work, available to all members of the community.

(C) Maintenance of employment—that is to say, avoidance of mass unemployment.

The paragraphs in the report which elaborate Assumption B are given in full below.

Comprehensive Health and Rehabilitation Services

426. The second of the three assumptions has two sides to it. It covers a national health service for prevention and for cure of disease and disability by medical treatment; it covers rehabilitation and fitting for employment by treatment which will be both medical and post-medical. Administratively, realization of Assumption B on its two sides involves action both by the Departments concerned with health and by the Ministry of Labour and National Service. Exactly where the line should be drawn between the responsibilities of these Departments cannot, and need not, be settled now. For the purpose of the present report, the two sides are combined under one head, avoiding the need to distinguish accurately at this stage between medical and post-medical work. The case for regarding Assumption B as necessary for a satisfactory system of social security needs little emphasis. It is a logical corollary to the payment of high benefits in disability that determined efforts should be made by the State to reduce the number of cases for which benefit is needed. It is a logical corollary to the receipt of high benefits in disability that the individual should recognize the duty to be well and to co-operate in all steps which may lead to diagnosis of disease in early stages when it can be prevented. Disease and accidents must be paid for in any case, in lessened power of production and in idleness, if not directly by insurance benefits. One of the reasons why it is preferable to pay for disease and accident openly and directly in the form of insurance benefits, rather than indirectly, is that this emphasizes the cost and should give a stimulus to prevention. As to the methods of realizing Assumption B, the main problems naturally arise under the first head of medical treatment. Rehabilitation is a new field of remedial activity with great possibilities, but requiring expenditure of a different order of magnitude from that involved in the medical treatment of the nation.

427. The first part of Assumption B is that a comprehensive national health service will ensure that for every citizen there is available whatever medical treatment he requires, in whatever form he requires it, domiciliary or institutional, general, specialist, or consultant, and will ensure also the provision of dental, ophthalmic and surgical appliances, nursing and midwifery, and rehabilitation after accidents. Whether or not payment towards the cost of the health service is included in the social insurance contribution, the service itself should (i) be organized, not by the Ministry concerned with social insurance, but by Departments responsible for the health of the people and for positive and preventive as well as curative measures; (ii) be provided where needed without contribution conditions in any individual case.

Restoration of a sick person to health is a duty of the State and the sick person, prior to any other consideration. The assumption made here is in accord with the definition of the objects of medical service as proposed in the Draft Interim Report of the Medical Planning Commission of the British Medical Association:

"(*a*) To provide a system of medical service directed towards the achievement of positive health, of the prevention of disease, and the relief of sickness; (*b*) to render available to every individual all necessary medical services, both general and specialist, and both domiciliary and institutional."

428. Most of the problems of organization of such a service fall outside the scope of the report. It is not necessary to express an opinion on such questions as free choice of doctor, group or individual practice, or the place of voluntary and public hospitals respectively in a national scheme. It is not necessary to express an opinion on the terms of service and remuneration of doctors of various kinds, of dentists and of nurses, except in so far as these terms may affect the possibility of diminishing and controlling sickness and so may affect the finances of the Social Insurance Fund. Once it is accepted that the administration of medical treatment shall be lifted out of social insurance to become part of a comprehensive health service, the questions that remain for answer in this report are, in the main, financial. Shall any part of the cost of treatment, and if so what part, be included in the compulsory insurance contribution? But, though that question is in itself financial, the answer to it may affect the organization of the service and may therefore depend in part upon views as to organization.

429. In dealing with this financial question, it is desirable to consider separately domiciliary treatment, institutional treatment, special services like dental and ophthalmic treatment, and subsidiary services such as supply of medical or surgical appliances, nursing and convalescent homes.

430. *Domiciliary treatment* is now paid for by persons subject to health insurance, for themselves by compulsory contributions, for dependants either by a charge for treatment when it is given or more rarely by voluntary contribution through associations for public medical service. There is no obvious reason, apart from a desire to keep the insurance contribution as low as possible, why insured persons should be relieved of this burden wholly, in order that they may bear it as tax-payers. If importance attaches to preserving the contributory principle for cash benefit, it attaches also to contribution for medical treatment. There appears to be a case for including part of the cost of domiciliary treatment in the insurance contribution. This means that a proportion of the receipts of the Social Insurance Fund would be paid by the Fund to the Health Departments as a grant towards the cost of the medical service. The administration of this money would rest with the Health Departments.

431. But one consequence of this suggestion has to be noted. The Report proposes a compulsory social insurance scheme without income limits. Its contributing Classes I, II, and IV, though they pay different contributions according to the cash benefits for which they insure, are not income classes; each contains rich and poor. Any contribution for medical treatment must apply to all these classes, to every one in each of them, and must cover their dependants in Class III (Housewives) and Class V (Children). If a contribution for medical treatment is included in the insurance contribution, contributions will cover not 90% of the population (the present insured persons and their dependants), as is assumed in the Draft Interim Report issued by the Medical Planning Commission, but 100% of the population. This will not, of itself, put an end to private practice. Those who have the desire and the means will be able to pay separately for private treatment, if the medical service is organized to provide that, as they may pay now for private schooling, though the public education system is available for all. But no one will be compelled to pay separately. The possible scope of private general practice will be so restricted that it may not appear

---

* Cmd. 6404. H.M. Stationery Office. (2s.)

worth while to preserve it. If, therefore, it is desired to preserve a substantial scope for private practice and to restrict the right to service without a charge on treatment to persons below a certain income limit, it will not be possible to include a payment for medical service in an insurance contribution which all are required to pay irrespective of income.

432. *Institutional treatment* is not included in the present health insurance contribution except to a small extent as an additional benefit. It is obtainable by any citizen in a public hospital subject to recovery of the cost—that is to say, to payment according to his means, or free if he has no means. It is obtainable in a private hospital, as a rule either in virtue of previous voluntary contribution through a hospital contributory scheme or on payment according to means as agreed with the hospital almoner. The growth of hospital contributory schemes in the years just before this war has been remarkable. They are stated to cover now more than 10,000,000 wage earners and they produce more than £6,500,000 a year for the voluntary hospitals; the cost of collecting this money is put at about 6%; in London and some other parts of the country contribution to a Hospital Saving Association qualifies the contributor for free treatment either in a voluntary hospital or in a public hospital as may best suit his case. The Ministry of Labour family budgets in 1937-8 showed an average payment to hospital saving associations of 3½d. a week in every industrial household and 3d. a week in every agricultural household. British people are clearly ready and able to pay contributions for institutional treatment. Should a payment for this purpose be included in the compulsory insurance contribution, and be passed on as a grant from the Social Insurance Fund to the Health Departments towards the maintenance of the institutions? The answer to this financial question, like the answer to the similar question as to domiciliary treatment, involves problems of organization as well as finance. If a payment for institutional treatment is included in the compulsory insurance contribution, there will be little or nothing left for which people can be asked to contribute voluntarily, and an important financial resource of the voluntary hospitals will come to an end. It will then be for the Health Departments to use the grant that they will receive from the Social Insurance Fund in whatever way best fits their hospital policy. If it is not included, people of limited means will have the choice, as at present, of contributing voluntarily beforehand or of paying at the time of treatment, according to means.

433. The main considerations relevant to the choice between these alternatives are:

(i) The importance of securing that suitable hospital treatment is available for every citizen and that recourse to it, at the earliest moment when it becomes desirable, is not delayed by any financial considerations. From this point of view, previous contribution is the ideal, better even than free service supported by the tax-payer. People will take what they have already paid for without delay when they need it, and they pay for it more directly as contributors than as tax-payers. But it can be argued that, under the present system, people do not in practice delay taking hospital treatment when they need it; their general practitioner will advise going to hospital, as soon as it becomes necessary, and if they are not voluntary contributors they will be asked to pay only according to their means. It is possible that the main practical reasons which now delay recourse to hospital after it has become desirable are not difficulties about paying for the treatment, but either (*a*) deficiency of accommodation or (*b*) unwillingness or inability to give up work or household duties in order to be treated. A suggestion for meeting the last-named difficulty is made in para. 344.

(ii) Hospital policy, particularly in relation to the place of voluntary hospitals, the terms of service and pay of their staffs, and the desirability or the reverse of allowing arrangements whereby individuals, whether through membership of a voluntary association or by special payment, can get choice of specialists or hospitals or special treatment in them.

(iii) Financial policy, and particularly the question of the optimum size of the insurance contribution and of the security budget in relation to the ordinary budget.

435. *Dental and ophthalmic treatment and appliances* are now overwhelmingly the most popular of the additional treatment benefits under national health insurance. That is to say, they are being paid for in part by compulsory contributions and for the rest mainly by a charge when treatment is given. There is a general demand that these services should become statutory benefits available to all under health insurance. There appears to be ground for regarding a development of preservative dental treatment as a measure of major importance for improving the health of the nation. This measure involves, first, a change of popular habit from aversion to visiting the dentist till pain compels into readiness to visit and be inspected periodically; it involves simultaneously, with creation by these means of a demand for a larger dental service, the taking of steps to organize a larger supply of the service. That the insurance title to free dental service should become as universal as that to free medical service is not open to serious doubt. The only substantial distinction which it seems right to make is in the supply of appliances. To ensure careful use, it is reasonable that part of the cost of renewals of dentures should be borne by the person using them. This might possibly be extended to the original supply. The same holds true of optical appliances.

436. *Surgical appliances, convalescent homes, and nursing* are less widely provided as additional benefits, but are essential to a comprehensive health service. Decision as to making these subsidiary services contributory or non-contributory for the individual depends on the line taken in regard to the major problems of domiciliary and institutional treatment. It is reasonable that insured persons should contribute something for such services, as they have shown themselves able and willing to do in the past; in regard to appliances of all kinds, the terms of supply and renewal must be such as to give an incentive to careful use. But it would be anomalous to require compulsory contributions for special and subsidiary purposes if the main services were non-contributory.

437. This review of some of the problems involved in establishing a comprehensive medical service makes clear that no final detailed proposals, even as to the financial basis of this service, can be submitted in this report. It suggests the need for a further immediate investigation, in which the finance and the organization of medical services can be considered together, in consultation with the professions concerned and with the public and voluntary organizations which have established hospitals and other institutions. From the standpoint of social security, a health service providing full preventive and curative treatment of every kind to every citizen without exceptions, without remuneration limit and without an economic barrier at any point to delay recourse to it, is the ideal plan. It is proposed accordingly that, in the contributions suggested as part of the Plan for Social Security, there shall be included a payment in virtue of which every citizen will be able to obtain whatever treatment his case requires, at home or in an institution, medical, dental, or subsidiary, without a treatment charge. It is proposed that the sums derived from these payments shall be transferred to the Department or Departments concerned with the organization of the health service to meet part—it can only be part—of the total cost. But these proposals are provisional only, subject to review in the light of the further inquiry suggested, in which organization and finance can be dealt with together. The primary interest of the Ministry of Social Security is not in the details of the national health service or in its financial arrangements. It is in finding a health service which will diminish disease by prevention and cure, and will ensure the careful certification needed to control payment of benefit at the rates proposed in this report.

438. Assumption B covers not only medical treatment in all its forms, but also *post-medical rehabilitation.* In regard to the latter, as in regard to the former, it would be inappropriate here to discuss details or organization. During the preparation of this report the practical problems of rehabilitation have been under consideration by the Departments concerned, and it is hoped that practical measures will follow. Rehabilitation is a continuous process by which disabled persons should be transferred from the state of being incapable under full medical care to the state of being producers and earners. This process requires close co-operation between the Health Departments and the Department concerned with employment—that is to say, the Ministry of Labour and National Service. Whether this co-operation can be secured best by the setting up of an executive organ representative of both sides or by allocation of specific duties to each Department is a problem of departmental organization on which it would

be inappropriate here to express an opinion. It is sufficient to put forward three general propositions:

(a) That rehabilitation must be continued from the medical through the post-medical stage till the maximum of earning capacity is restored, and that a service for this purpose should be available for all disabled persons who can profit by it irrespective of the cause of their disability.

(b) That cash allowances to persons receiving rehabilitation service should be the same as training benefit, including removal and lodging allowances where required.

(c) That the contributions paid by insured persons should, as in the case of medical treatment, qualify them for rehabilitation service without further payment.

Correspondence

Hand and Finger Lesions

SIR,—During recent months a great deal of correspondence has appeared in your columns on complacency in anaesthetics. May I call attention to another branch of medical practice—the treatment of injuries and infections of the hand and fingers—where complacency is the only explanation of, though no excuse for, the deplorable results which are so often met with?

It has been estimated that in peacetime injuries of the hand and fingers were responsible for 35 to 45% of the total sum paid as compensation for all injuries, and at a meeting of the British Orthopaedic Association at Nottingham on Sept. 25 and 26 Dr. Donald Stewart stated (Oct. 24, p. 493) that of 1,000 consecutive accidents in one factory 52% were finger injuries only. It is the same story in the Services, where these lesions cause longer hospitalization, a higher degree of permanent disability, and more invaliding than almost any other condition. A small part of the blame for the poor results may be due to the severity of the original injury or to the failure of the patient to present himself in time for treatment to be effective, but impartial analysis forces one to the unpleasant conclusion that by far the greater share of the blame is due to neglect or mismanagement by the patient's medical advisers.

An open wound of the finger is no less worthy of skilled and careful treatment than an open fracture of the femur, but too often it is classed among the trivialities of minor surgery. Medical men who would never dream of using a scalpel for any other purpose gaily "operate" on these cases without any adequate attempt at asepsis and with little or no appreciation of the principles which should govern their treatment. This attitude is understandable, for these lesions receive little attention in the curriculum of most medical schools. Students see injuries and infections of the fingers left to the most junior hospital officers and more or less ignored by the honorary staff.

Improvement will only be attained if all those who are responsible for the surgical education of students take more trouble than most of them do at present to show by their teaching and example the importance and seriousness of lesions of the fingers. It is fortunate that there is no subject that lends itself more to dogmatic teaching, for it is one of the very few exceptions where theoretical knowledge is more important than experience or technical ability. Good results can be obtained by anyone who is prepared to learn and obey a few cardinal principles: careful pre-operative examination; perfect asepsis at operation and re-dressings; a dry field; the avoidance of incisions in the mid-line of the finger, buried sutures or ligatures, rubber drains, fomentations, baths, or passive movements; immobilization of the affected parts in the position of function, and mobilization of the unaffected fingers, etc.

The education of those who are already qualified is a more difficult task, but there is a way in which I believe it could be done. Since the beginning of the war a spate of literature has poured out from the medical departments of the fighting Services, the Medical Research Council, and the E.M.S. instructing us what to do and what not to do for this and that condition. Of the educational value of these memoranda there can be no doubt. Is it too much to hope that one or other of these bodies, or better still a joint committee representing them all, will formulate and issue a memorandum on "The Principles of the Surgery of the Hand and Fingers"?—I am, etc.,

J. B. OLDHAM,
Surg. Commander, R.N.V.R.

The Sulphonamide Problem

SIR,—Surg. Cmdr. E. A. Gerrard's letter (Nov. 28, p. 647) about the uses and abuses of the sulphonamide group of drugs is most timely. The general public appears to regard the use of these drugs from one of two aspects: either as a veritable elixir of life which no one must neglect to employ or as a kind of last rite in a desperate emergency. From the professional point of view the situation is scarcely less unhappy. Within a very short period instances have come to my notice of the administration of sulphonamides to an infant cutting teeth, to cases of septic finger of minor degree, and to a patient with a small boil in the axilla. The dose employed in this last case could not have caused the slightest inconvenience to any but a moribund staphylococcus, though the patient proved much more vulnerable to its action. The use of sulphonamide powder in recent wounds is in danger of being regarded as a substitute for and not as an additional safeguard to careful excision. Now that the powder is recommended as a first-aid dressing steps should be taken to ensure that proper excision of the wound should not be delayed or neglected on this account.

Sufficient information is now available for the preparation of a survey of this group of drugs. This might be undertaken by an authoritative body such as the Medical Research Council, and the production of a film, preferably in colour, should be considered. A film on this subject has been made in America but has not yet reached this country. By the kindness of one of the manufacturing firms a colour film on the treatment of pneumonia was recently shown in this area. So great was the interest aroused that there occurred what one only too rarely sees at a medical meeting—a "full house." I believe in this way we have an ideal method of dealing with an urgent problem quickly, scientifically, and in a manner to arouse the greatest interest.—I am, etc.,

Berkhamsted R. GRAINGER, F.R.C.S.

Ship-borne Small-pox

SIR,—It is apparent that the story of the outbreak of small-pox in Glasgow, 1942, is not ended. Following the introduction of ship-borne infection into that city the possibility has now arisen that small-pox may once again become endemic in these islands. A similar situation threatened to develop after the arrival of the *Tuscania* at Glasgow in April, 1929, and of the *Cathay* at the Port of London in March, 1938. On each occasion infection was carried and spread ashore.

Small-pox on a ship at sea is an example of an infectious disease occurring in a closed community, where conditions are almost ideal for containing the epidemic. I suggest that, at a time when this country is free from small-pox, a case may be made out for enforcing absolute quarantine on an infected ship. This measure, combined with the efficient use of vaccination, should determine the outbreak within twenty-one days.—I am, etc.,

Dartford, Kent J. PICKFORD MARSDEN.

Cleft Palate

SIR,—Mr. H. P. Pickerill (May 30, p. 680) has taken me to task for some remarks I made in an article on cleft palate published in the *British Journal of Surgery* (Oct., 1941), and he has set me some interesting questions to answer. I must apologize for my delay in replying, but the *Journal* containing his letter has only just reached me.

I was a little disappointed that a surgeon of Mr. Pickerill's experience should consider "extravagant" my strong condemnation of the use of a tubed pedicle graft for repairing a cleft palate, but I read the description of his cases treated by intra-oral tubed pedicles with great interest. Mr. Pickerill's first two cases were not examples of cleft palate but of gunshot wounds of the palate; my paper did not include a description of wounds of the palate. I agree that gunshot wounds with enormous loss of tissue might require operations which I should characterize as fantastic if used for the repair of the smaller congenital defects. Though my unit has recently treated a number of gunshot wounds involving the palate, we have yet to see a case which required a tubed pedicle graft for the repair of the palate.

I still consider repair of any type of congenital defect in the palate by means of a tubed pedicle graft to be a fantastic operation, and I believe Mr. Pickerill when he says that these procedures "tax the skill of the operator to the utmost in their final stages." It seems to me that the patience and forbearance of the patient are even more severely taxed than the skill of the operator, for the patient, following the operation, has to sustain a pedicle attached at one end to the palate and at the other, presumably, to some part of the upper extremity or chest for ten to fourteen days. Yet Mr. Pickerill says of these operations: "They certainly do not, as stated, cause pain to the patient." I cannot believe that Mr. Pickerill does not visit his patients on the day after operation.

Not having seen her I cannot say what I should have done for the "young woman" under Mr. Pickerill's care who was "panic-stricken" at the prospect of the dental extractions which were to rob her obturator of its sole support. Possibly her panic was in part due to Mr. Pickerill's proposal that he should attach her arm to her palate by a tubed pedicle. I can well imagine Mr. Pickerill's satisfaction at the gratitude and pleasure of the parents of the boy who was "the leader of his school in sport and study" when a tubed pedicle enabled him to acquire good speech. But would a Wardill or a Gillies-Fry procedure have earned the gratitude and pleasure not only of the proud parents but also of the boy himself? I think it might have done.

I do congratulate Mr. Pickerill on his great technical skill in the performance of these elaborate operations. I congratulate Mrs. Pickerill even more heartily, not only for reconstructing the lip and palate of the baby mentioned with anatomical perfection but also for saving the poor child from one of Mr. Pickerill's tubed pedicle operations.—I am, etc.,

MICHAEL C. OLDFIELD,
M.E.F. Major, R.A.M.C.

The Teaching of First Aid

SIR,—The importance of a widespread knowledge of the elements of first aid in present circumstances is generally acknowledged; but, owing to the existence side by side of two distinct official systems, lecturers and examiners are confronted by a handicap which, one would think, ought to be removed at least for the duration of the war.

No one would urge the British Red Cross Society and the St. John Ambulance Association to merge their separate identities—each has its own special field of service—but the present liaison might, I think, be drawn even closer in one respect for the time being. As a lecturer under both systems, I have become more and more impressed by the advantages which would accrue from a common first-aid syllabus and a conjoint examination held under the auspices of both bodies. This would obviate the necessity for hard-pressed doctors to bear in mind two separate procedures. Moreover, it would eliminate the contretemps which sometimes arises when an examiner more conversant with Red Cross methods is appointed to examine a St. John class and vice versa, canalize into one channel energies now dissipated in two directions, and simplify the problems of intending students.

With a little give-and-take on both sides the difficulties of such a readjustment should not prove insuperable. If desired, the original position could be restored after the war, though possibly the advantages of one official system combining the best points of the two would by then have become so obvious that the change might become a permanent arrangement.—I am, etc.,

Grasmere E. W. ADAMS.

Control of Venereal Disease

SIR,—I would endorse the recommendations given by Drs. David Erskine and V. E. Lloyd (Nov. 21, p. 617), particularly the last sentence that the problem might well be discussed now so that suitable arrangements can be prepared in advance. In the Services the compulsory treatment which is so desirable can be effected without any difficulty and with none of the troubles attending on seeming publicity in similar circumstances in civilian life.

With regard to the new Defence Regulation 33B, I would submit that there are some serious defects which will prevent its being of use in many cases. First, it is the experience of many clinics at present that false names and addresses are frequently given by those attending; particularly is this so among men. It would be desirable, and may even become necessarily compulsory, to demand the production of the National Registration identity card on first attendance at the clinics. Authorities concerned might well be advised to practise this at present, even though they have no powers to compel its production. The identification of suspected persons to be named by two separate patients will obviously be prejudiced if fictitious names and addresses persist. Secondly, I am told that it is seldom that persons are named by those who attend—the element of fear of breach of "treatment in secrecy" obviously prevents such notification. The almoner of one large clinic assures me that there is the greatest difficulty, even when dealing with numbers and not names, in tracing contacts. It would seem unlikely that registration will therefore be as effective until a wider power to enforce observation and treatment becomes law.—I am, etc.,

Nailsea, Nr. Bristol. W. ARTHUR GORNALL, M.D.

SIR,—In the issue of your *Journal* for Nov. 21 you say with regard to the number of persons who fail to continue treatment for V.D.: "Major Laird points out that the defaulter rate of England in 1935 at 82.5% compares most unfavourably with the corresponding defaulter rate of 2.5% for Sweden." Yet the report of the Chief Medical Officer of Health for 1937 has the following: "The percentage of patients on the books of the treatment centres who discontinued attendance prematurely during the ten years ending December 31, 1937, were as follows":

	Syphilis		Gonorrhoea	
	Males	Females	Males	Females
1928	24.7	22.8	27.5	20.4
1931	24.2	22.2	29.3	21.2
1934	21.9	20.7	23.9	22.9
1937	17.4	17.9	21.8	18.2

If the average percentage of all patients defaulting in 1934 is just over 22%, and just over 18% in 1937, it is curious that it should have leapt to such a figure in 1935. There is no mention of this extraordinary rise in the Minister's report for 1935.—I am, etc.,

E. M. TURNER,
London, S.W.1. Secretary, Association for Moral and Social Hygiene

*** The statement in Major Laird's paper, summarized in the leading article, was as follows: "An investigation in various parts of Staffordshire, in which I collaborated, showed that in 1937 50% of cases of early syphilis and 30% of gonorrhoea cases defaulted. Sir Kingsley Wood stated that the percentage of clinic patients in England completing treatment and tests of cure was 12.9% in 1925 and 17.5% in 1935. This puts the defaulter rate for England in 1935 at 82.5%, which compares most unfavourably with 2.5%, the corresponding defaulter rate for Sweden." (*Brit. J. vener. Dis.*, 1942, 18, 84.)—ED., *B.M.J.*

Prostatic Smear as a Test for Cure of Gonorrhoea

SIR,—The cure of gonorrhoea is so important from the social and individual health points of view that it is not surprising that physicians have recourse to as many tests as possible in order to establish it with certainty. Of these procedures there is one which seems to me too dangerous in its sequelae and therefore not deserving of such widespread use in the venereal disease centres of this country—namely, the expression of prostatic fluid by massage for microscopical examination. The positive value is questionable, since the direct demonstration of gonococci in this liquid is fraught with so many contingencies that it is purely a matter of chance. Of course the bacteriological culture would considerably enhance the value of the test, but it is seldom practised in the routine work of a busy centre because it is too expensive and time-consuming. But even if this more scientific and accurate method be used, it is still doubtful whether the results would outweigh the possible harmful effects of prostatic massage, for in the early stage of gonorrhoea the maltreatment of the prostatic gland with its spongy structure is a serious matter if gonococci have already invaded it. Any rough handling of the prostate at this stage is the most certain method of disseminating the gonococci from the initial focus to the utmost recesses of the gland, with the additional risk of spreading the infection to the seminal vesicles. We are not entitled to draw analogies from similar procedures in the case of chronic prostatitis, where massage may yield useful therapeutic results, because in the latter case we are dealing with a type of chronic abscess in which an inflammation of long standing has become localized by means of a surrounding organized inflammatory infiltration, which prevents the possible spread of the infection. In recent acute gonorrhoea any interference with an infected prostate is as dangerous and risky as squeezing a furuncle in the acute stage.

It is certain that in many cases where the material obtained by efficient and therefore forceful massage of the prostatic gland yields a positive result, the subsequent prostatitis and potential vesiculitis are the direct outcome of this exploration, although they may erroneously be regarded as a confirmation of the diagnosis. When it is remembered that the incidence of gonococcal arthritis and rheumatism accounts for about 10% of all cases of chronic arthritis—one of the widely prevalent diseases in this country—and that gonococcal arthritis nearly always indicates the presence of latent prostatitis and/or vesiculitis, it is clear that this whole question deserves thorough consideration and discussion.

Recent experience with the sulphonamide group of drugs suggests that the considerable reduction of chronic complications in gonorrhoea may be due not only to the rapid therapeutic effect obtained, but also, and in no less degree, to the omission of direct interference with the urethra, such as lavage, instillations, etc. Perhaps this point should be borne in mind when prostatic massage is being considered as a control test for the cure of gonorrhoea.—I am, etc.,

Polish Forces. JERZY FEINER.

Child Health

SIR,—Dr. James Burnet's letter (Nov. 21, p. 616) applies, *pari passu*, to the School Medical Service. This service, established in 1908 under the Education (Administrative Provisions) Act, was stultified from the beginning by being placed under the control of medical officers of health, who are seldom clinicians and as a rule know little and care less about diseases of children. The sad result of this is that, as a general rule, the School Medical Service has become the poor relation in the Public Health Departments.

It is to be hoped that after the war the School Medical Service will be separated from Public Health Departments and established as a separate service under a clinician with special knowledge of diseases of children; and, further, that medical inspection will be carried out in special centres, properly equipped and staffed, away from school buildings, and that existing "care committees" will be abolished and "following up" of cases done by trained nurses.—I am, etc.,

Sunninghill, Berks. EVA MCCALL.

Loneliness in Infancy

SIR,—I have been greatly interested in the correspondence on loneliness in infancy, and in particular in Dr. Laura Hutton's letter (Nov. 7, p. 558). It certainly seems strange that mothers should deny to infants that ordinary degree of consideration that they would show to their adult acquaintances. To leave a baby to scream is, I agree, criminal, though it requires some experience to tell what exactly is the matter. In nine cases out of ten something very specific is the matter, and can fairly easily be remedied. Infant routine has become, to an illogical extent, dominated by the clock. I can see no merit, however, in a routine which recommends three- or four-hourly feeds and yet allows for a long interval of eight (or more) hours at night, even for newborn babies. Only the baby knows how hungry it is, and to deny it food when it asserts its hunger is a cruelty that one would not practise with more articulate beings.

I would, however, like to join issue with Dr. Hutton on two points. First, with regard to thumb-sucking. I have had four babies in the past six years. All have been treated with a fair degree of leniency, the leniency becoming greater as my experience increases. The two younger babies have not been allowed to cry for more than a very short time before a rescue is effected. Nevertheless, all four have been thumb-suckers. I do not like to think of this as a sign of special mental imbalance. In fact, it seems to me to be a very normal baby pastime, and one that should give rise to no anxiety in the parents, especially if it disappears when the baby starts to handle and play with toys. It seems possible that many very well adjusted people may have been thumb-suckers in their early childhood. No definite evidence has, so far as I know, been produced either to confirm or to deny this possibility.

The same lack of evidence can, I think, be held against Dr. Hutton's implication that loneliness in infancy necessarily gives rise to neurotic personality in later life. I should be interested to know whether so-called normal people have not suffered much the same deprivations as those who require analytical help, but have not reacted so unfavourably to them. Have many really well-adjusted people undergone thorough and deep analysis?

I raise these points largely to reassure myself, as mistakes in dealing with infants cannot be avoided. With Dr. Hutton's general thesis that ordinary consideration is too often denied to very young babies I concur whole-heartedly; and wish that something could be done to re-educate the public away from the clock and back to natural impulse.—I am, etc.,

Stansted, Essex. NANCY SALAMAN.

Tonsillectomy by Guillotine and Dissection

SIR,—In my article on this subject (Oct. 31, p. 512) I dealt with the methods of tonsillectomy. Dr. E. C. Atkinson's letter (Nov. 21, p. 620) illustrates well the die-hard aspect of some dissectionist schools. Three-quarters of his long letter is devoted to a discussion of the removal of adenoids, which has nothing to say to the case. I must not trespass on your space to discuss its inaccuracies.—I am, etc.,

Guildford. T. B. JOBSON.

*** This correspondence is now closed.—ED., *B.M.J.*

Future of the Profession

SIR,—Dr. H. E. Collier's excellent letter (Nov. 14, p. 591) on the future of the profession raises important points with regard to medical planning. The spate of letters on this subject has stressed medical organization; there is no mention of actual medical work. A co-ordinated medical service with good working conditions for doctors is undoubtedly needed, but it will not solve our true medical problems. The object of this service will be the maintenance of a healthy population, but how can we hope to achieve this by organizational changes alone?

The futility of our present medical approach—our clinical examination with its growing battery of static investigations—is obvious in all cases save those of established disease. Will the general practitioner, working in a health centre and personally able to follow his patient through hospital investigation, be any better off when "organic disease is excluded" and he still has a patient with real symptoms and complaints on his hands? Will the maternity and child welfare worker be better able to deal with the numbers of physically subnormal children who attend our welfare centres? Will the pathologist with his increasing studies of the infinite variations of bacteria help us much unless we see the need for an equally careful study of individual variations in the subjects whom bacteria attack?

Unless we realize that alteration of our outlook and technique must be part of our reorganization, medicine will remain sterile, irrespective of the framework within which it functions.—I am, etc.,

ROWENA WOOLF,
